## Abstract

We present a graduate course on ideal measurements, analyzed as dynamical processes of interaction between the tested system  $S$  and an apparatus  $A$ , described by quantum statistical mechanics. The apparatus  $A=M+B$  involves a macroscopic measuring device  $M$  and a bath  $B$ . The requirements for ideality of the measurement allow us to specify the Hamiltonian of the isolated compound system  $S+M+B$ . The resulting dynamical equations may be solved for simple models. Conservation laws are shown to entail two independent relaxation mechanisms: truncation and registration. Approximations, justified by the large size of  $M$  and of  $B$ , are needed. The final density matrix  $\hat{D}(t_f)$  of  $S+A$  has an equilibrium form. It describes globally the outcome of a large set of runs of the measurement. The measurement problem, i.e., extracting physical properties of individual runs from  $\hat{D}(t_f)$ , then arises due to the ambiguity of its splitting into parts associated with subsets of runs. To deal with this ambiguity, we postulate that each run ends up with a distinct pointer value  $A_i$  of the macroscopic  $M$ . This is compatible with the principles of quantum mechanics. Born's rule then arises from the conservation law for the tested observable; it expresses the frequency of occurrence of the final indications  $A_i$  of  $M$  in terms of the initial state of  $S$ . Von Neumann's reduction amounts to updating of information due to selection of  $A_i$ . We advocate the terms  $q$ -probabilities and  $q$ -correlations when analyzing measurements of non-commuting observables. These ideas may be adapted to different types of courses.

## Résumé

On présente un cours doctoral sur les mesures idéales, processus dynamiques couplant le système testé  $S$  et un appareil  $A$  analysés en mécanique statistique quantique. Cet appareil  $A=M+B$  comprend un dispositif de mesure macroscopique  $M$  et un bain  $B$ . Les conditions requises pour l'idéalité de la mesure impliquent une forme spécifique du Hamiltonien du système composite isolé  $S+M+B$ . Les équations dynamiques résultantes sont solubles pour des modèles simples. Les lois de conservation engendrent deux mécanismes de relaxation indépendants, la troncature et l'enregistrement. Des approximations, justifiées par la grande taille de  $M$  et de  $B$ , sont nécessaires. La matrice densité finale  $\hat{D}(t_f)$  de  $S+A$  a une forme d'équilibre. Elle décrit globalement l'issue d'un large ensemble de processus similaires. Le problème de la mesure, extraire de  $\hat{D}(t_f)$  des propriétés physiques de processus individuels, provient ici de l'impossibilité de le scinder sans ambiguïté en parties décrivant des sous-ensembles de processus. On lève cette ambiguïté en postulant que chaque mesure individuelle aboutit à une valeur distincte  $A_i$  du pointeur macroscopique. Ceci est compatible avec les principes de la mécanique quantique. La règle de Born résulte alors de la loi de conservation de l'observable mesurée; elle exprime la fréquence de chaque indication finale  $A_i$  de  $M$  en termes de l'état initial de  $S$ . La réduction de von Neumann apparaît comme une mise à jour de l'information résultant de la sélection d'un résultat  $A_i$ . On préconise l'emploi des termes  $q$ -probabilités ou  $q$ -corrélations lors de l'analyse de mesures d'observables non-commutatives. Ces idées peuvent être adaptées à divers types de cours.

Keywords: ideal quantum measurements,  $q$ -probability, system-apparatus dynamics, measurement problem, Born rule, von Neumann reduction, minimalist interpretation, contextuality

Mots clefs: mesures quantiques idéales,  $q$ -probabilités, dynamique système-appareil, problème de la mesure, règle de Born, réduction de von Neumann, interprétation minimaliste, contextualité

## 1. INTRODUCTION

Most courses of quantum mechanics include lectures on ideal measurements, defined as thought processes characterized by Born’s rule and von Neumann’s reduction of the state. Students may be puzzled by this topic, as these two properties are often presented as separate basic principles, while reduction may seem to contradict Schrödinger’s equation. [1, 2]. Clarifying the status of such properties is pedagogically important, since they greatly contribute to the understanding of quantum mechanics. This issue is a current concern of teachers, who tackle it from many different viewpoints. We propose here a consistent approach that has been tested on graduate students and that might also inspire courses at less advanced levels. It relies on the standard quantum dynamics for the macroscopic apparatus coupled to the tested system, complemented with a postulate about the apparatus which affords a solution of the measurement problem.

### 1.1. Interpretation, ideal measurement, apparatus and dynamics

The quantum formalism encodes in a mathematical language our knowledge about the systems under study, and affords efficient predictions. However, this description is abstract, and relating it to physical reality requires an interpretation. The literature devoted to this matter is immense, often subtle, and encompasses many different viewpoints (for reviews, see [3–10]). Students should get acquainted with the subject, which includes understanding of Born’s rule and von Neumann’s reduction, but some specific approach suitable for teaching must be selected.

By “interpretation”, we will mean a complete theoretical analysis of thought processes that relate the quantum formalism to experimental facts (§ 6.5 (c)). The study of measurements thus provides insight on quantum theory. It helps to grasp how physical knowledge about a tested object can be derived from its mathematical representation.

As we wish to fully work out the theory of a measurement process, we should consider a sufficiently simple situation. A current approach, initiated by Jordan and von Neumann [11], consists in focusing on “ideal quantum measurements”. They are dynamical processes through which a single observable of the system S is tested by an apparatus A, and such that S is not perturbed by its interaction with A if it initially lies in an eigenstate of this observable. They involve many runs, starting alike but possibly yielding one or another among several different outcomes<sup>1</sup>. They will be defined more precisely in § 3.1 and § 5.1.

As an illustrative example, we consider the so-called Curie-Weiss model [12, 13]. There, we imagine measuring the  $z$ -component  $s_z$  of S, a spin  $\frac{1}{2}$ , by letting S interact with an Ising ferromagnet A initially in a metastable paramagnetic state. If  $s_z = +1$  (or  $-1$ ), the process should keep  $s_z$  unchanged, while triggering the pointer, which is here the  $z$ -component  $M_z$  of the macroscopic total magnetization of A, so that it finally takes the value  $M_z = +M_F$  (or  $M_z = -M_F$ ). We wish to explore the situation in which the initial state of S is arbitrary. A detailed introduction to this magnetic model and its complete treatment are presented in ref. [13], which also includes a wide review of other measurement models.

A general model describing arbitrary ideal measurements is specified in § 3. Laboratory measurements rarely satisfy these features [14–16], and we should regard ideal measurements, also called quantum non-demolishing measurements, as thought experiments. However, their analysis provides ideas relevant to real measurements.

We designate as “apparatus” A the *complete* experimental setup coupled to S. The idealized system A includes a measuring device M which models the whole experimental machinery, including detectors that afford registration and reading, and a thermal bath B, often called “environment” or “context”, which will ensure equilibrium at the issue of the process. The compound system S+A, which contains the bath B, is isolated, which will allow to describe its evolution through the Liouville–von Neumann equation of motion.

Consistency requires that the joint evolution of S+A obeys standard quantum mechanics, both S and A being treated as quantum objects. However, A is *macroscopic*, involving a huge number of degrees of freedom. Moreover, the dynamical process is *irreversible* on the timescales of physical interest. These two reasons exclude a description by means of pure states. Since the macroscopic apparatus A cannot be described in detail, we must rely on quantum *statistical* mechanics and use density operators. This also allows to treat a mixed state for S, the most general case. The final density operator<sup>2</sup>  $\hat{D}(t_f)$  of S+A thus determined is expected to express how the indication of M reflects a property of S. However, it is still a formal object, and it will remain to face interpretation issues (§ 1.2 and § 6).

---

<sup>1</sup> Measurement theory then provides the relative frequency of occurrence of each possible outcome. If one considers a single process, this frequency is identified with the probability of occurrence of the considered result.

<sup>2</sup> Quantum mechanical operators are indicated by a hat.

## 1.2. The measurement problem

Consider a given observable  $\hat{s}$  of the system S with eigenvalues  $s_i$  and suppose that S has been prepared in such a way that  $\hat{s}$  takes the (non-degenerate) value  $s_1$  among its set of eigenvalues  $s_i$ . This property characterizes the fact that S is in a pure state represented by the eigenstate  $|\psi_1\rangle$  of  $\hat{s}$  (or by the density operator  $\hat{r}_1 = |\psi_1\rangle\langle\psi_1|$ ). Then, in an ideal measurement of  $\hat{s}$ , the joint dynamics of S+A, after interaction of S with A, leaves S unchanged while M is modified. Its pointer variable reaches, among the possible macroscopic indications  $A_i$ , the value  $A_1$  associated with  $s_1$ , revealing the initial property of S (§ 3.2.3). Thus, the quantum system M should be chosen so as to involve a *measurement basis* (§ 3.2.1), the elements of which are in one-to-one correspondence with the eigenvalues  $s_i$ , this correspondence being ensured by the form of the coupling between S and M (§ 3.2.2).

Non-classical features appear if the state  $\hat{r}$  of S, whether pure or not, is not an eigenstate of  $\hat{s}$ . Then, if a measurement of  $\hat{s}$  is performed on different samples S, all prepared in the same initial state  $\hat{r}(0)$  at the initial time  $t_i = 0$ , a subsequent ideal measurement of  $\hat{s}$  is expected to provide, at the final time  $t = t_f$  of each individual run, different possible outcomes  $i$ . The set  $\mathcal{E}$  of runs can thus be separated into subsets  $\mathcal{E}_i$ . Both S and A, in particular the pointer of M, are modified. The subset  $\mathcal{E}_i$  gathers the runs with outcome  $A_i$  of the pointer of M, which occur with some probability  $p_i$ , and for which S ends up in a final state  $\hat{r}_i$  (§ 3.1 and 5.1). The celebrated *measurement problem* [9] arises from the apparent contradiction between the uniqueness of the initial state and the non-uniqueness of the final state.

In fact, what we call “quantum state”, whether pure or not, is in general an abstract mathematical object which allows us to make probabilistic predictions about the outcomes of any experiment that will test the object under study, for arbitrary observables. It encodes everything that we can say about this object, and is related only indirectly to its physical properties (§ 2). It is thus irreducibly probabilistic: even the above pure state  $|\psi_1\rangle$  is a probabilistic mathematical object with regard to observables other than  $\hat{s}$ , as their measurement on different samples all described by  $|\psi_1\rangle$  will yield different answers, the probabilities of which are determined by  $|\psi_1\rangle$ .

Thus, within the “frequentist” interpretation of probabilities, a quantum state refers to a large set of similar systems<sup>1</sup>. In particular, the density operator  $\mathcal{D}(t)$  of S+A associated with an ideal quantum measurement process does not describe only a single operation, but a large set  $\mathcal{E}$  of similarly prepared individual runs<sup>3</sup>.

The density operator  $\hat{\mathcal{D}}(t_f)$  describing S+A at the issue of the interaction process, for the full set of runs, can be determined in the framework of quantum statistical mechanics. One has to solve the equation of motion for  $\hat{\mathcal{D}}(t)$ , with a known initial condition on  $\hat{\mathcal{D}}(0)$  (§ 4).

We wish to derive from  $\hat{\mathcal{D}}(t_f)$  the features of *individual runs of a measurement*, in particular to understand von Neumann’s reduction, which characterizes the different final states  $\hat{r}_i$  of S that may occur in the various runs, and Born’s rule, which expresses their relative number  $p_i$ . However, as will be discussed in § 5.2, the object  $\hat{\mathcal{D}}(t_f)$  cannot yet be interpreted physically, although it contains the  $\hat{r}_i$ ’s and  $p_i$ ’s as ingredients. It is a *mathematical* tool describing, *only globally*, the outcome of the *large set of runs* of the ideal measurement. Its sole knowledge is not sufficient to ensure the very existence of subsets for which the pointer of the apparatus takes some macroscopic value  $A_i$  and to extract the required information about *individual runs*. This peculiarity of density operators in the standard quantum formalism is the mathematical form taken here of the measurement problem. It is stated more precisely in § 5 below.

To face this mismatch, we will supplement the standard formal quantum rules with an idea issued from macroscopic experience. Namely, we acknowledge that *each individual run* of the measurement produces a *single macroscopic indication of the pointer of the apparatus* which may be read or registered (§ 5.3). This statement, although intuitive, is not a consequence of the mere quantum principles and has a macroscopic nature. We will accept its inclusion in quantum theory as a *postulate* (motivated by the macroscopic size of M), and also show its *full consistency* with the quantum formalism (§ 6.1). We shall then be in position to interpret  $\hat{\mathcal{D}}(t_f)$ , splitting it into meaningful terms (§ 5.4) and to derive therefrom the expected properties of ideal measurements (§ 6).

## 1.3. Overview

We present below the scheme of various courses about the dynamics and the interpretation of ideal measurements which have been delivered by one or another of us at Universities or Summer Schools. The full approach is suited to advanced students, having some knowledge of quantum statistical mechanics, but basic ideas deserve to be retained in more elementary courses. The length of the text is partly due to inclusion of details and remarks issued from questions

---

<sup>3</sup> Note that Bell [17, 18] advocated to replace the word “measurement” by “experiment”; he argued that speaking of “measurement” incites to refer to some pre-existing property of the sole object, irrespective of the apparatus.

of students. Complementary exercises are proposed; some may be inspired by numerous models which describe the joint evolution of S+A. The present text, somewhat sketchy and abstract, is intended for teachers. They may construct a course suited to their audience by finding inspiration in refs. [13, 19], which contain more explanations, a review of solvable models and a detailed treatment of the Curie–Weiss model, with illustrative figures that should help the understanding.

We first resume the *principles* of quantum statistical mechanics in a form suited to this problem (§ 2). In particular, we regard a “state” as an abstract tool gathering our whole knowledge (Bohr’s “catalog of knowledge”) of a large set of systems, in view of making probabilistic predictions. It has some features of ordinary probability distributions but should not be confused with them. We also recall its dynamical equation and the definition of von Neumann’s entropy.

We then recall the expected properties of ideal measurements and define a *general model* for them (§ 3.1). The compound object under study involves the tested system S and the apparatus A, in which we distinguish the measuring device M and the thermal bath B. Relying on the conditions needed to ensure that the interaction process between S and A behaves as an ideal measurement, we specify in § 3.2 the required form of the Hamiltonian of S+M+B. (This tripartite model, suited for our purpose, is not the only one that can be imagined.)

In § 4.1 we write the expression of the initial state  $\hat{D}(0)$  of S+M+B and the form taken by the equations of motion, taking into account the conservation laws. The final state  $\hat{D}(t_f)$  should be determined dynamically from these data. Students acquainted with statistical mechanics may study, for various solvable models, the relaxation of  $\hat{D}(t)$  to find the explicit form of  $\hat{D}(t_f)$  (§ 4.2 and Appendices A, B, C) [13]. Suited exercises are proposed. For less advanced courses, we propose a more expedient and general procedure, relying on a *thermodynamic approach* (§ 4.3).<sup>4</sup> Namely, keeping aside the bath and describing by the marginal state  $\hat{D} = \text{tr}_B \hat{D}$  the system S+M weakly coupled to B, we first derive the general form of the *thermodynamic equilibrium* states  $\hat{D}_{\text{eq}}$  of S+M, obtained by maximizing von Neumann’s entropy. We then identify the dynamics of the measurement process with a relaxation towards thermodynamic equilibrium. Thus, the final state  $\hat{D}(t_f)$  belongs to this equilibrium class, and we determine it by using conservation laws.

As indicated above (§ 1.2) and explained in § 5, we then have to face the measurement problem: the final density operator  $\hat{D}(t_f)$  found for S+M for the *full set*  $\mathcal{E}$  of runs cannot readily be separated into parts that would describe the result of *individual runs* of  $\mathcal{E}$  (§ 5.2). But by relying on experimental evidence, we postulate that the value of the pointer is macroscopically well-defined for each run (§ 5.3). This allows us to split  $\hat{D}(t_f)$  into physically meaningful parts (§ 5.4).

We can thus derive the properties of the outcomes of ideal measurements (§ 6), stressing that their physical interpretation depends crucially on the apparatus (§ 6.4). Although  $\hat{D}(t_f)$  does not have the same properties as a standard probability distribution (§ 2.1.3), the coefficients  $p_i$  entering  $\hat{D}(t_f)$  will come out as ordinary probabilities  $p_i$ , understood as relative frequencies of the possible outcomes  $A_i$  for the pointer at the final time  $t_f$ . Born’s rule, which expresses these  $p_i$ ’s in terms of the initial state of S, will appear as a consequence of the joint dynamics and of the conservation laws (§ 6.3). Von Neumann’s reduction will be interpreted as an updating of the state of S based on the knowledge of  $A_i$  (§ 6.4).

We conclude (§ 7) by suggesting which parts of this text seem adapted to such or such level of teaching, from introductory courses of quantum mechanics to doctoral studies.

## 2. QUANTUM PRINCIPLES

We noted in § 1.1 that the analysis of measurement processes requires quantum statistical mechanics. Among the many formulations of quantum theory, we recall its principles in a form suited to that purpose [21]. When being taught, the rules resumed below should be illustrated by examples.

### 2.1. Mathematical structures

The mathematical structure of the quantum formalism involves two dual spaces, that of “observables” and that of “states”, abstract objects related only indirectly to the corresponding physical entities (§ 6.5 , point (a)) [22].

---

<sup>4</sup> This “thermodynamic approach” differs from Neumaier’s “thermal interpretation” of quantum mechanics [20], although both analyses rely on the consideration of macroscopic variables and the use of quantum statistical mechanics.

### 2.1.1. Observables

The physical quantities attached to a given type of system are called “*observables*”, and mathematically represented by operators  $\hat{O}$  belonging to a non-commutative algebra.<sup>5</sup> For the systems with a finite number of degrees of freedom that we are considering, the observables can be represented by Hermitean matrices ( $\hat{O} = \hat{O}^\dagger$ ) in a Hilbert space  $\mathcal{H}$ . Their eigenvalues are expected to be tested by inference from the macroscopic outcomes of measurements.

### 2.1.2. States and sets of systems

As indicated in § 6.5, quantum theory does not describe in general individual systems, but an *infinitely large collection*  $\mathcal{E}$  of similarly prepared systems, real or possibly virtual. For such a collection, the quantum formalism associates, at each time, a numerical value  $\langle \hat{O} \rangle$  with each physical quantity represented by an observable  $\hat{O}$ . This correspondence, which is a mathematical representation of a “*quantum state*”, is formally defined as a linear mapping  $\hat{O} \mapsto \langle \hat{O} \rangle$  (for  $\hat{O} = \hat{O}^\dagger$ ), such that  $\langle \hat{I} \rangle = 1$  for the unit observable  $\hat{I}$ , that  $\langle \hat{O} \rangle$  is real and that  $\langle \hat{O}^2 \rangle - \langle \hat{O} \rangle^2 \geq 0$ . For systems with a finite number of degrees of freedom, it can be expressed in the form

$$\langle \hat{O} \rangle = \text{Tr } \hat{D} \hat{O}, \quad (1)$$

by a *density operator*  $\hat{D}$  in the (self-dual) Hilbert space  $\mathcal{H}$ . In a given basis,  $\hat{D}$  is represented by means of a *density matrix* which is Hermitean, non-negative and normalized.<sup>6</sup> Pure states  $|\psi\rangle$ , whose density operators are projectors  $\hat{D} = |\psi\rangle\langle\psi|$  on a one-dimensional subspace of  $\mathcal{H}$ , appear as extreme points of the convex set of states  $\hat{D}$  (see end of Appendix D). Contrary to what it often done in elementary courses, we do not assign them a more fundamental status nor a special interpretation.

The above formalism presents some analogy with the standard probability theory. Observables  $\hat{O}$  look like random variables, states  $\hat{D}$  like probability distributions, and (1) like expectation values. However, this analogy is purely formal (§ 1.2 and § 2.1.4). Not only mathematical properties but also basic concepts are different for the two theories. We shall rely here on the interpretation of ordinary probabilities [23] as *frequencies of occurrence of exclusive events* (such as heads or tails), which take place among an infinitely large set of individual draws, whereas quantum theory involves *non-exclusive* properties, such as the polarization of a spin  $\frac{1}{2}$  along  $+z$  or along  $+x$ . Hence, the overall properties of a quantum state do not comply with ordinary probability theory. Accordingly, it will be essential below (§ 5) to carefully distinguish the *infinitely large collection*  $\mathcal{E}$  of individual systems, or of individual runs of an experiment, from a “*statistical ensemble*”, governed by the ordinary probability theory. Such a set  $\mathcal{E}$ , described by a quantum state  $\hat{D}$ , is just a collection of similar elements, while a *statistical ensemble* is an infinitely large set of systems which display exclusive events that *may be counted* to define probabilities. “Observables” and “states” are mathematical symbols without yet a physical interpretation. They will give rise to genuine probabilities (in the sense of relative frequencies) at the issue of measurement theory (§ 6.1), but only for the single tested observable.

### 2.1.3. Physical meaning of a quantum state

Students should not be misled by the term, “state”, currently used to designate the mathematical object  $\hat{D}$ , and difficult to avoid when teaching. Its meaning should be made clear. Whether “pure” or not, the so-called “quantum state of a system” is not an intrinsic physical property of an individual system. We advise to avoid the expression “the wave function of the particle”. As stressed by Bohr [24, 25], a “state”  $\hat{D}$  is just a *mathematical tool* which encompasses “*what we can say*” about a large set of systems, allowing us to make *probabilistic predictions* about future experiments. As indicated above, we adhere here to the interpretation of a probability as the relative *frequency* of occurrence of each type of event, in a large set of events [25]. However, the results of our approach will eventually apply to *individual* processes, if one relies on the Laplace – Bayes interpretation where a probability appears as a *likelihood* (see [13], § 10.1.3).

One should never forget that a quantum state, represented by a density operator, a density matrix, a pure state or a wave function, is an *abstract object* encoding our *best knowledge about the set of systems* under consideration.<sup>7</sup>

<sup>5</sup> Mathematically, observables are self-adjoint elements of a  $C^*$ -algebra, a structure which involves an addition  $\hat{A}_1 + \hat{A}_2$ , a product  $\lambda \hat{A}$  by complex numbers  $\lambda$ , a non-commutative multiplication  $\hat{A}_1 \hat{A}_2$ , a unit element  $\hat{I}$ , an involution that defines conjugate pairs  $\hat{A} \leftrightarrow \hat{A}^\dagger$ , a norm  $\|\hat{A}\|$ , together with consistency rules such as associativity  $\hat{A}_1(\hat{A}_2 \hat{A}_3) = (\hat{A}_1 \hat{A}_2) \hat{A}_3$  and distributivity  $\hat{A}_1(\hat{A}_2 + \hat{A}_3) = \hat{A}_1 \hat{A}_2 + \hat{A}_1 \hat{A}_3$ .

<sup>6</sup> We shall indifferently use the terms “state”, “density operator” and “density matrix”.

<sup>7</sup> The *best knowledge* may even differ for different observers, who rely on their available data to assign different states to a set of systems (§ 2.3). More complete knowledge leads to more optimal predictions for future experiments, as will be exemplified in § 6.3.

### 2.1.4. Probabilities versus $q$ -probabilities

Consider the special case of a single observable  $\hat{O} \equiv \sum_{\alpha} \omega_{\alpha} \hat{\pi}_{\alpha}$  of a system S (with eigenvalues  $\omega_{\alpha}$  and eigen-projectors  $\hat{\pi}_{\alpha}$ ) and of a density operator  $\hat{D}_{\alpha}$  belonging to the eigenspace  $\alpha$  of  $\hat{O}$  (i. e., constrained to satisfy  $\hat{D}_{\alpha} \equiv \hat{\pi}_{\alpha} \hat{D}_{\alpha} \hat{\pi}_{\alpha}$  or  $\text{Tr} \hat{D}_{\alpha} \hat{\pi}_{\alpha} = 1$ ). Then, the number  $\langle \hat{O} \rangle = \text{Tr} \hat{D}_{\alpha} \hat{O} = \omega_{\alpha}$  (with  $\langle \hat{O}^2 \rangle - \langle \hat{O} \rangle^2 = 0$ ) is identified with the *physical value*  $\omega_{\alpha}$  taken by the quantity  $\hat{O}$  in the considered state. As will be proven in § 3.2.3, subsequent measurements of  $\hat{O}$  keep  $\hat{D}_{\alpha}$  unchanged and will again yield  $\omega_{\alpha}$ .

Still considering a single observable  $\hat{O}$  but an arbitrary density operator  $\hat{D}$ , we will analyze below an ideal measurement process testing  $\hat{O}$ , where S interacts with an apparatus A, both S and A being treated as quantum objects. This will lead us (§ 6.2) to interpret, but *only for this single observable*, the quantities  $p_{\alpha}$  formally defined by  $p_{\alpha} = \text{Tr} \hat{D} \hat{\pi}_{\alpha}$  as relative frequencies of occurrence of the values  $\omega_{\alpha}$  and hence  $\langle \hat{O} \rangle = \text{Tr} \hat{D} \hat{O} = \sum_{\alpha} p_{\alpha} \omega_{\alpha}$  as an ordinary expectation value.

However, such an interpretation fails as soon as we measure *several non-commuting* observables. For instance, for a  $q$ -bit (whose observables are the Pauli matrices  $\hat{\sigma}_{1,2,3}$  of a spin  $\frac{1}{2}$ ), the occurrences of the four possible values  $s_z = \pm 1$ ,  $s_x = \pm 1$  do not constitute a sample space of four exclusive events to which probabilities might be assigned, in contrast to the two alternative values of an ordinary bit. If we consider the 4 projectors  $\hat{\pi}_{\lambda}$  associated with the events  $s_z = \pm 1$ ,  $s_x = \pm 1$ , we cannot regard the 4 quantities  $\text{Tr} \hat{D} \hat{\pi}_{\lambda}$  as probabilities of exclusive events.

To discuss such questions, the traditional vocabulary is a source of confusion. Whenever we deal with non-commuting observables, and already in introductory courses, we advocate to name “ $q$ -probabilities” rather than “probabilities” the formal quantities  $\langle \hat{\pi} \rangle = \text{Tr} \hat{D} \hat{\pi}$  (on the model of  $q$ -bit versus bit).<sup>8</sup> Likewise, as observables are directly expressed in terms of projectors, the quantities  $\langle \hat{O} \rangle = \text{Tr} \hat{D} \hat{O}$  should be called “ $q$ -expectation values”. For a *single product*  $\hat{O} = \hat{O}_1 \hat{O}_2$  of commuting observables,  $\langle \hat{O}_1 \hat{O}_2 \rangle$  may be regarded as a correlation, but for several products  $\hat{O} = \hat{O}_1 \hat{O}_2$ ,  $\hat{O}' = \hat{O}'_1 \hat{O}'_2$ ,  $\hat{O}'' = \hat{O}''_1 \hat{O}''_2$ ,  $\dots$ , such that  $\hat{O}$ ,  $\hat{O}'$ ,  $\hat{O}''$ ,  $\dots$ , do not commute, the set  $\langle \hat{O}_1 \hat{O}_2 \rangle$ ,  $\langle \hat{O}'_1 \hat{O}'_2 \rangle$ ,  $\langle \hat{O}''_1 \hat{O}''_2 \rangle$ ,  $\dots$ , should systematically be called “ $q$ -correlations”, as they do not have *together* the properties of correlations. For instance they violate Bell’s inequalities [17, 26–28] that constrain ordinary correlations. This would help the students to grasp quantum properties which *violate rules of ordinary probabilities* (Bell’s inequalities [17, 26–28]) or even seem to violate logic (GHZ paradox [29]). In such cases, apparently paradoxical quantum properties arise from combining several *formal*  $q$ -correlations that involve non-commuting observables. In fact, the determination of such different  $q$ -correlations requires measurements performed on *different samples* by *different apparatuses*, so that we cannot interpret them *together* as physical correlations (§ 6.4). The misleading term “correlations” suggests fake paradoxes. Likewise, the two “ $q$ -variances” entering Heisenberg’s inequality  $\langle \hat{O}_1^2 \rangle \langle \hat{O}_2^2 \rangle \geq \frac{1}{4} |[\hat{O}_1, \hat{O}_2]|^2$ , which has a quantum nature, are neither “uncertainties” nor ordinary “variances”, as testing them refers to incompatible measurements involving different apparatuses.

In fact, even for a single observable, it is of pedagogical interest to denote formal quantities computed from a quantum state as  $q$ -probabilities, since they reach a physical meaning only after recording through measurement. Indeed, we will show in § 6 how the ideal measurement of a *single observable* of S allows us to interpret the  $q$ -probabilities associated with its eigen-projectors as ordinary probabilities (in the sense of relative frequencies). This property relies on the interaction of S with a macroscopic *dedicated apparatus*. Measuring two non-commuting observables requires different apparatuses, the outcomes of which cannot be put together to produce ordinary probabilities.

## 2.2. Basic laws

The laws of quantum theory (§ 6.5, point (b)) are expressed by mathematical operations on density operators.

### 2.2.1. Evolution

The time dependence of the density operator  $\hat{D}(t)$  of an *isolated* system (such as S+A) is generated by a Hamiltonian  $\hat{H}$  which depends on the nature of the system. It is governed by the Liouville–von Neumann dynamical equation

$$i\hbar \frac{d\hat{D}(t)}{dt} = [\hat{H}, \hat{D}(t)], \quad (2)$$

<sup>8</sup> The mathematical structure of these so-called “quantum probabilities”, which differs from that of ordinary probabilities, will not be presented here. The Boolean algebra describing elementary events in ordinary probability theory is replaced by the “lattice structure” of the set of non-commutative projectors, with which the above formal quantities are associated. The standard interpretations of probabilities in terms of elementary physical events are then lost.

reducing to the Schrödinger equation  $i\hbar d|\psi\rangle/dt = \hat{H}|\psi\rangle$  for pure states  $|\psi\rangle$  represented by a projector  $\hat{\mathcal{D}} = |\psi\rangle\langle\psi|$ .

### 2.2.2. Subsystems

For a compound system described by the state  $\hat{\mathcal{D}}$ , here the union of the tested system S and the apparatus A, the marginal density matrices  $\hat{r}$  and  $\hat{\mathcal{R}}$  which describe the subsystems S and A are obtained from  $\hat{\mathcal{D}}$  by taking the *partial traces*  $\hat{r} = \text{tr}_A \hat{\mathcal{D}}$  and  $\hat{\mathcal{R}} = \text{tr}_S \hat{\mathcal{D}}$  over A and S, respectively.<sup>9</sup>

### 2.2.3. Merging of sets

Consider two large sets  $\mathcal{E}_1$  and  $\mathcal{E}_2$  of similar systems, described in the Hilbert space  $\mathcal{H}$  by given states  $\hat{\mathcal{D}}_1$  and  $\hat{\mathcal{D}}_2$ , respectively. Merging  $\mathcal{N}_1$  elements extracted from  $\mathcal{E}_1$  and  $\mathcal{N}_2$  elements extracted from  $\mathcal{E}_2$  produces a new set  $\mathcal{E}$  gathering the  $\mathcal{N} = \mathcal{N}_1 + \mathcal{N}_2$  elements. The compound set  $\mathcal{E}$  is described (as in ordinary probability theory) by the weighted sum

$$\mathcal{N}\hat{\mathcal{D}} = \mathcal{N}_1\hat{\mathcal{D}}_1 + \mathcal{N}_2\hat{\mathcal{D}}_2. \quad (3)$$

However, the *converse is wrong*, as will be demonstrated in § 5.2 and Appendix D. Given a density operator  $\hat{\mathcal{D}}$  that represents some set  $\mathcal{E}$  of systems, we cannot infer from a *mathematical* decomposition  $\hat{\mathcal{D}} = \lambda_1\hat{\mathcal{D}}_1 + \lambda_2\hat{\mathcal{D}}_2$  as a weighted sum that  $\hat{\mathcal{D}}_1$  and  $\hat{\mathcal{D}}_2$  represent *physical* subsets of  $\mathcal{E}$ , although  $\hat{\mathcal{D}}_1$  and  $\hat{\mathcal{D}}_2$  have the properties of density operators (§ 2.1.2). This specifically quantum property must be faced to solve the measurement problem (§ 5).

### 2.2.4. Von Neumann entropy

In agreement with the definition (1) of a state  $\hat{\mathcal{D}}$  as a catalogue of probabilistic knowledge about a large collection of systems, one associates with it the von Neumann entropy<sup>10</sup>,

$$S(\hat{\mathcal{D}}) \equiv -\text{Tr} \hat{\mathcal{D}} \ln \hat{\mathcal{D}}, \quad (4)$$

a number which measures (in dimensionless units) the *amount of information* which is missing when only  $\hat{\mathcal{D}}$  is specified [30]. Roughly speaking, it can also be viewed as a measure of disorder. It will be used to assign a state to a partially known set of systems (§ 2.3 and § 4.3.1) and to estimate the loss of information carried by the density operator of S+A, due to the irreversibility of the measurement process (Appendix C) as well as the gain of information about S (§ 6.3).

## 2.3. Preparation

The preparation of a large collection  $\mathcal{E}$  of systems at a given time, in view of performing future experiments, is physically ensured by an apparatus which imposes some data to  $\mathcal{E}$ , and theoretically accounted for by assigning to  $\mathcal{E}$  a density operator  $\hat{\mathcal{D}}$ . We shall encounter this issue in several circumstances.

A preparation is characterized by some *given data*, imposed to all the systems of the set  $\mathcal{E}$ . Each one is implemented as a *constraint* on the state  $\hat{\mathcal{D}}$  that we wish to specify. For instance, if a preparation apparatus which controls the physical quantity  $\hat{O} \equiv \sum_{\alpha} \omega_{\alpha} \hat{\pi}_{\alpha}$  imposes that it always takes the value  $\omega_{\alpha}$ , the state  $\hat{\mathcal{D}}$  must satisfy the constraint  $\text{Tr} \hat{\mathcal{D}} \hat{\pi}_{\alpha} = 1$  (§ 2.1.4), meaning that the value  $\omega_{\alpha}$  is determined by  $\hat{\mathcal{D}}$  with certainty. (We expect in this case that the outcome of a measurement of  $\hat{O}$  will be  $\omega_{\alpha}$ , see § 3.2.3.) In the limit of very large systems, we may also deal with *macroscopic data*, defined not exactly but within a negligible uncertainty. For instance, the macroscopic energy  $E$  of a thermal bath (with Hamiltonian  $\hat{H}$ ) is given by the  $q$ -expectation  $\text{Tr} \hat{\mathcal{D}} \hat{H} = E$ , where  $E$  lies within the dense spectrum of  $\hat{H}$ , the large size of the bath allowing the  $q$ -fluctuation of energy around  $E$  to be negligible in relative value at the macroscopic scale. The macroscopic indication of the pointer (§ 3.1) will have the same features: dense spectrum, negligible  $q$ -fluctuation.

<sup>9</sup> We denote by  $\text{Tr}$  a scalar obtained by taking the trace of an operator over the full associated Hilbert space, and by  $\text{tr}$  an operator obtained by taking a partial trace over a compound Hilbert space. For instance, if  $\hat{X}$  acts in the compound Hilbert space  $\mathcal{H}_{SA} = \mathcal{H}_S \otimes \mathcal{H}_A$ ,  $\text{tr}_A \hat{X}$  is an operator acting in the Hilbert space  $\mathcal{H}_S$  and we have  $\text{Tr} \hat{X} \equiv \text{Tr}_{SA} \hat{X} = \text{Tr}_S (\text{tr}_A \hat{X}) = \text{Tr}_A (\text{tr}_S \hat{X})$ .

<sup>10</sup> We take units in which the Boltzmann constant equals  $k = 1$ .

When such constraints are imposed through the control of a complete set of commuting observables, they fully determine the state  $\hat{D}$  (which is then pure). Otherwise, and especially for macroscopic systems, various density operators  $\hat{D}$  are compatible with the known data, and one should select among them the *least biased* one by means of a probabilistic argument. This choice relies on the *maximum entropy criterion* [31–33] based on the identification of the von Neumann entropy (4) as a measure of randomness: The sought density operator  $\hat{D}$  is the one that maximizes  $-\text{Tr} \hat{D} \ln \hat{D}$  under the given constraints.<sup>11</sup> In case the data are expectation values that do not change over time, this procedure yields a *thermodynamic equilibrium state* (§ 4.3); if the sole constraint is  $\text{Tr} \hat{D} \hat{H} = E$ , it yields a canonical equilibrium state  $\hat{D} \sim \exp(-\beta \hat{H})$  (Eqs. (6), (7)).

### 3. A MODEL FOR IDEAL MEASUREMENTS AND ITS FORMAL IMPLEMENTATION

The above principles cannot be given any direct and complete interpretation, although some have already been given an interpretation (beginning of §§ 2.1.4, 2.2.4 and 2.3). What we will interpret below, in agreement with contextuality, is only the result of measurements.

In the continuation, we will first analyse in the above quantum formalism the dynamics of idealized experiments that may be regarded as ideal measurements (§ 4). We will then search for a physical interpretation of the outcome of the process, in order to finally clarify the physical meaning of Born’s rule and of von Neumann’s reduction which characterize ideal measurements (§ 6). We gather here beforehand their specific physical features, sometimes subtle but needed, and build a general model on which our subsequent study of the measurement process will rely. These various features are exemplified by the Curie-Weiss model [13], which can be used throughout to illustrate them.

#### 3.1. Physical requirements

The purpose is to *explore the properties of an observable*<sup>12</sup>  $\hat{s} \equiv \sum_i s_i \hat{\pi}_i$  (with eigenvalues  $s_i$  and eigen-projectors  $\hat{\pi}_i$ ) of a system S described by a given density operator  $\hat{r}(0)$  at the initial time  $t_i = 0$ , by letting S interact with a dedicated apparatus. Moreover, the ideal measurement process as defined in § 1.1 should *perturb S as little as possible* (§ 3.2.2). To this aim, S is dynamically coupled to an idealized apparatus A dedicated to this task. We distinguish two parts A=M+B in this apparatus. The part M is a *measuring mechanism* including a *macroscopic pointer* that should eventually display outcomes  $A_i$  in one-to-one correspondence with  $s_i$  at the final time  $t_f$  of the process. A *thermal bath* B weakly coupled to M will contribute to the equilibration of S+M.

This idealized experiment consists of *many repeated runs*.<sup>13</sup> The large set  $\mathcal{E}$  of compound quantum systems S+A = S+M+B involved in these runs is described at the time  $t$  by a state  $\hat{D}(t)$  in the Hilbert space  $\mathcal{H} = \mathcal{H}_S \otimes \mathcal{H}_M \otimes \mathcal{H}_B$ . We shall denote by  $\hat{r}$ ,  $\hat{R}_M$ ,  $\hat{R}_B$ ,  $\hat{R}$  and  $\hat{D}$  the marginal density operators (§ 2.2.2) of the subsystems S, M, B, A=M+B and S+M in their respective Hilbert spaces  $\mathcal{H}_S$ ,  $\mathcal{H}_M$ ,  $\mathcal{H}_B$ ,  $\mathcal{H}_A = \mathcal{H}_{MB}$  and  $\mathcal{H}_{SM}$ , e. g.,  $\hat{D} = \text{tr}_B \hat{D}$ ,  $\hat{r} = \text{tr}_M \hat{D}$ . As M and B must be *macroscopic*, states such as  $\hat{D}(t)$ ,  $\hat{R}_M(t)$  or  $\hat{D}(t)$  *cannot be pure*<sup>14</sup>, a fact already stressed in § 1.1. The *Hamiltonian*  $\hat{H}$  governing the dynamics of the isolated system S+M+B can be decomposed as<sup>15</sup>

$$\hat{H} = \hat{H}_S + \hat{H}_A + \hat{H}_{SM}, \quad \hat{H}_A = \hat{H}_M + \hat{H}_B + \hat{H}_{MB}, \quad (5)$$

into parts associated with the three subsystems and with their interactions.

The measuring device M should have the following physical property. For each run, it should end up at the time  $t_f$  in one or another of some *stable states*  $\hat{R}_i$ , which are often called “*pointer states*”, characterized by the *macroscopic indication*  $A_i$  of the pointer, which can be read or registered within a proper time window. The pointer variable is represented quantum mechanically by an observable  $\hat{A}$  of M, and each outcome by a narrow region of the spectrum of  $\hat{A}$  centred around the value  $A_i$ . Each state  $\hat{R}_i$  should thus exhibit  $A_i$  as the  $q$ -expectation value  $A_i = \text{tr}_M \hat{R}_i \hat{A}$  of  $\hat{A}$ , while the relative fluctuation of  $\hat{A}$  in  $\hat{R}_i$  should be negligible for large M.

<sup>11</sup> This use of the von Neumann entropy in the determination of the least biased state  $\hat{D}$  can be justified by taking as a prior distribution in the space of states the one that is invariant under unitary transformations, then by relying on the indifference (or equiprobability) principle of Laplace. This procedure produces the same result  $\hat{D}$  as the maximum entropy criterion [34].

<sup>12</sup> For instance, for a spin  $\frac{1}{2}$ ,  $\hat{s}_z = \hat{\pi}_\uparrow - \hat{\pi}_\downarrow$  with  $\hat{\pi}_\uparrow = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$  and  $\hat{\pi}_\downarrow = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$  has the eigenvalues  $\pm 1$ .

<sup>13</sup> This large number of runs is not only a standard experimental feature, but is also theoretically needed because the quantum formalism cannot describe an individual measurement (§ 2.1.2). In fact, Born’s probabilities refer to a large set of runs; they represent the relative number of runs that have provided each possible outcome.

<sup>14</sup> A pure state, or a wave function, cannot be assigned to a macroscopic system like an apparatus. Characterizing a piece of material by a pure state would require control of an unrealistic number of variables.

<sup>15</sup> More precisely, as  $\hat{H}$  acts in the full Hilbert space  $\mathcal{H} = \mathcal{H}_S \otimes \mathcal{H}_A$  and  $\hat{H}_S$  in the Hilbert space  $\mathcal{H}_S$  of S,  $\hat{H}_S$  in (5) is a short hand for  $\hat{H}_S \otimes \hat{I}_A$ , where  $\hat{I}_A$  is the unit operator in the Hilbert space  $\mathcal{H}_A$ . And likewise for all other terms in (5). We shall use the same simplified notation in the continuation.

One wishes the interaction process between M and S to produce at the final time a *one-to-one correspondence* between the outcome  $A_i$  of  $\hat{A}$  and the measured eigenvalue  $s_i$  of  $\hat{s}$ . In particular, if the tested system S is initially prepared in a state  $\hat{r}(0)$  such that  $\hat{s}$  takes the value  $s_i$  with certainty, the subsequent interaction  $\hat{H}_{SM}$  between M and S should *trigger the evolution of M* towards the pointer state  $\hat{R}_i$ , despite the macroscopic size of M and the smallness of S, which should remain unaffected. This is possible in case M had beforehand been prepared in a *metastable initial state*  $\hat{R}_M(0)$  which may decay towards one or another stable state  $\hat{R}_i$ , depending on a small perturbation. We will implement this property in the general model of ideal measurement considered below.

The *bath* B will contribute to the relaxation of M through the weak coupling  $\hat{H}_{MB}$ , which allows dumping of free energy from M to B during the process. This bath, at temperature  $T$ , described by the thermal equilibrium state (end of § 2.3),

$$\hat{R}_B \sim \exp\left(-\frac{H_B}{T}\right), \quad (6)$$

is sufficiently large so that its marginal density operator  $\text{tr}_{SM}\hat{D}(t) = \hat{R}_B(t) \simeq \hat{R}_B$  remains nearly unchanged throughout the process. We recall that the initial state of the apparatus A,  $\hat{R}_M \otimes \hat{R}_B$ , is a *mixed* state.

### 3.2. Features of the Hamiltonian

Some specific conditions must be satisfied by M so that it can be used as a measuring device, and by the interactions between S, M and B so that their coupled dynamics can be regarded as an ideal measurement process. We construct here the general form (5) of the Hamiltonian of the compound system S+M+B needed to ensure the required properties of ideal measurements.

Let us first specify the properties of the Hamiltonian of the apparatus A=M+B alone required so that M acts as an ideal measuring device.

#### 3.2.1. Apparatus alone

The existence for M of *several* possible final pointer states  $\hat{R}_i$  as well as the existence of an initial *metastable* state  $\hat{R}_M(0)$  imply that M is macroscopic and should be ensured by some specific form of its own Hamiltonian  $\hat{H}_M$ . These features also require that the system M is macroscopic. The different states  $\hat{R}_i$  must stand on the same footing to avoid bias in the measurement, so that the macroscopic energies  $U_i = \text{tr}_M \hat{R}_i \hat{H}_M$  should be the same as well as the entropies  $S(\hat{R}_i)$ . A simple means of ensuring such properties consists in assuming that the Hamiltonian  $\hat{H}_M$  possesses some *symmetry which is broken at the temperature T* of the bath.<sup>16</sup>

The implementation of this property may be illustrated for students by the Curie–Weiss model, studied in detail in [13]. In that thought experiment, the apparatus A alone is simulated by a piece of ferromagnetic material, modelled as a system M of  $N$  spins  $\frac{1}{2}$  with Ising interaction, weakly coupled to a phonon bath B at temperature  $T$ . The Hamiltonian  $\hat{H}_M$  is invariant under the exchange  $+z \leftrightarrow -z$ , and the pointer observable  $\hat{A}$  of M is the total magnetization  $\hat{M}_z$  along the  $z$ -direction, proportional to  $N$ . If  $T$  lies below the Curie temperature  $T_C$ , the paramagnetic initial state  $\hat{R}_M(0)$  of M (with  $\langle \hat{M}_z \rangle = 0$ ) is metastable, and two ferromagnetic equilibrium states  $\hat{R}_i$  exist, namely  $\hat{R}_\uparrow$  and  $\hat{R}_\downarrow$  which are characterized by the values  $\langle \hat{M}_z \rangle = +M_F$  and  $-M_F$ , respectively.<sup>17</sup> Beyond the application to measurements, the selection of one state  $\hat{R}_i$  of M or the other is usually achieved by considering a situation in which a weak magnetic field directed towards either  $+z$  or  $-z$  is applied to M. A source term  $\hat{h}_\uparrow = -g\hat{M}_z$  (or  $\hat{h}_\downarrow = g\hat{M}_z$ ) which breaks the symmetry  $+z \leftrightarrow -z$  is thus added to  $\hat{H}_M$ . The state  $\hat{R}_\uparrow$  (or  $\hat{R}_\downarrow$ ) is obtained by letting  $g$  become small *after* the

<sup>16</sup> The group of transformations that keeps  $\hat{H}_M$  invariant under permutation of the indices  $i$ , which is the parity  $+z \leftrightarrow -z$  for the Curie–Weiss model with spin  $\frac{1}{2}$ , has been non-trivially generalised to higher spins [35].

<sup>17</sup> We refer to the directions  $+z$  and  $-z$  by using double arrows  $\uparrow$  and  $\downarrow$  for M (e.g.  $\hat{R}_\uparrow$  or  $\hat{R}_\downarrow$ ) and single arrows  $\uparrow$  and  $\downarrow$  for S (e.g.  $\hat{\pi}_\uparrow$ ).

number  $N$  of magnetic spins is made large.<sup>18</sup>

Likewise, in the general case, we wish to formally define each expected possible final equilibrium state  $\hat{R}_i$  of  $M$ . As explained in footnote 18, we cannot do that by considering the sole Hamiltonian  $\hat{H}_M$ . To this aim, we first add as above a small *source term*  $\hat{h}_i$  to its Hamiltonian  $\hat{H}_M$ . This produces the single equilibrium state<sup>19</sup>

$$\hat{R}_i^h = \frac{1}{Z_i} \exp\left(-\frac{\hat{H}_M + \hat{h}_i}{T}\right). \quad (7)$$

(This introduction of operators  $\hat{h}_i$  may look artificial, but its relevance to measurement will be explained in § 3.2.2.) Denoting by  $A_i^h$  the  $q$ -expectation value of the pointer operator  $\hat{A}$  in the state  $\hat{R}_i^h$ , we select the operators  $\hat{h}_i$  in such a way that the corresponding  $q$ -fluctuations are small compared to the differences between the values  $A_i^h$ . We then let each small source  $\hat{h}_i$  decrease, remembering that  $M$  is very large. For a suitable choice of  $\hat{H}_M$  and sufficiently low  $T$ , the states  $\hat{R}_i^h$  shift only slightly, so as to reach *different limits*  $\hat{R}_i$ , as in the case of materials with broken invariance. The macroscopic pointer variable  $A_i$  appears as the limit of the  $q$ -expectation value

$$\text{Tr}_M \hat{R}_i^h \hat{A} \rightarrow \text{Tr}_M \hat{R}_i \hat{A} = A_i. \quad (8)$$

(For the Curie-Weiss model,  $A_i = M_{zi} = \pm M_F$ .)

Concerning the full apparatus  $A = M + B$ , we do not need here to specify the Hamiltonian  $\hat{H}_B$  of the bath  $B$  nor its weak interaction  $\hat{H}_{MB}$  with  $M$ , as we admit below (§ 4.3) that this coupling ensures the relaxation of  $S+M$  towards thermodynamic equilibrium. The operators  $\hat{H}_B$  and  $\hat{H}_{MB}$  are defined for models [13] in which the dynamics of this relaxation can be treated by statistical mechanics (§ 4.2). As the pointer variable must change during this process,  $\hat{H}_{MB}$  should not commute with  $\hat{A}$ . (In the Curie-Weiss model,  $\hat{H}_{MB}$  induces transitions between eigenstates of  $\hat{H}_M$  which involve neighboring eigenvalues of the magnetization per spin  $\hat{m} = \hat{M}/N$ .)

### 3.2.2. Coupling between the system and the apparatus

We noted (§ 3.1) that the evolution of the macroscopic apparatus  $M$  towards one  $\hat{R}_i$  or another is driven by its coupling  $\hat{H}_{SM}$  with the tested system  $S$ . In return,  $S$  is also generally perturbed by its coupling with  $M$ . We have defined (§ 1.1) an ideal measurement as a process for which this perturbation is minimal (i. e., it is absent if  $\hat{r} = \hat{\pi}_i \hat{r} \hat{\pi}_i$ ). Let us determine the general form of  $\hat{H}_{SM}$  that fulfils this requirement.

First, in an ideal experiment the dynamics in the Heisenberg picture should not affect the tested observable  $\hat{s}$ . This is expressed by the commutation  $[\hat{H}, \hat{\pi}_i] = 0$  of the full Hamiltonian with the eigen-projectors  $\hat{\pi}_i$  of  $\hat{s}$ , i.e.,  $\hat{\pi}_i \hat{H} \hat{\pi}_j = 0$  for  $i \neq j$ .<sup>20</sup> This conservation law is an essential feature of ideal measurements, already stressed by Wigner and Yanase [37]. Moreover, in case eigenvalues of  $\hat{s}$  are degenerate, dynamics should *not affect* the observables  $\hat{x}$  of  $S$  *physically compatible with*  $\hat{s}$ . This compatibility is expressed by the commutation of  $\hat{x}$  with all eigen-projectors  $\hat{\pi}_i$  of  $\hat{s}$ . Hence, besides the  $\hat{\pi}_i$ 's, the conserved quantities are the set

$$\hat{x} = \sum_i \hat{\pi}_i \hat{y} \hat{\pi}_i, \quad (9)$$

where  $\hat{y}$  is any arbitrary Hermitean operator in  $\mathcal{H}_S$ . (For example, if  $S$  is a pair of spins or  $q$ -bits  $S'$ ,  $S''$  and if the measured quantity is  $\hat{s}'_z$ , the observables  $\hat{x}$  are all linear combinations of  $\hat{s}'_z$ ,  $\hat{s}''_x$ ,  $\hat{s}''_y$ ,  $\hat{s}''_z$ ,  $\hat{s}'_z \hat{s}''_x$ ,  $\hat{s}'_z \hat{s}''_y$  and  $\hat{s}'_z \hat{s}''_z$ .) The required *conservation laws*  $[\hat{H}, \hat{x}] = 0$  in the space  $\mathcal{H}$  then entail that  $[\hat{\pi}_i \hat{H} \hat{\pi}_i, \hat{y}] = 0$ , for each  $i$  and for any  $y$  in the space  $\mathcal{H}_S$ . This implies that the operator  $\hat{\pi}_i \hat{H}_{SM} \hat{\pi}_i$  should have the form  $\hat{\pi}_i \otimes \hat{K}_i$ , where  $\hat{K}_i$  acts only in the Hilbert

<sup>18</sup> Strictly speaking, maximization of the von Neumann entropy  $S(\hat{R}_M)$  for a given energy (§ 2.3) yields the single thermodynamic equilibrium state  $\hat{R}_{\text{eq}} \propto \exp(-\hat{H}_M/T)$ , with entropy  $S_{\text{eq}}$ . The states  $\hat{R}_{\uparrow}$  and  $\hat{R}_{\downarrow}$  have an entropy  $S(\hat{R}_{\uparrow}) = S(\hat{R}_{\downarrow})$  nearly equal to  $S_{\text{eq}}$  for large  $N$ , as  $\hat{R}_{\text{eq}}$  is very close to  $\frac{1}{2}(\hat{R}_{\uparrow} + \hat{R}_{\downarrow})$ . The state  $\hat{R}_{\uparrow}$  ( $\hat{R}_{\downarrow}$ ) is located in a subspace  $\mathcal{H}_{\uparrow}$  ( $\mathcal{H}_{\downarrow}$ ) of  $\mathcal{H}_M$  spanned by a set of eigenvectors of  $\hat{M}_z$  associated with eigenvalues that lie around  $+M_F$  ( $-M_F$ ), within a small interval of relative size  $1/\sqrt{N}$ . The dimension  $\mathcal{N} \sim \exp S_{\text{eq}}$  of  $\mathcal{H}_{\uparrow}$  ( $\mathcal{H}_{\downarrow}$ ) is exponentially large in  $N$ . Then, although the function  $S(\hat{R}_M)$  is concave, its maximum  $S_{\text{eq}}$  is nearly flat. The entropy  $S_{\text{eq}}$  is practically reached for the huge set of density matrices  $\hat{R}_{\text{maxent}}$  located in the space  $\mathcal{H}_{\uparrow} \oplus \mathcal{H}_{\downarrow}$  and having a dimension of order  $\mathcal{N}$ . However, if the Hamiltonian  $\hat{H}_M$  contains weak interactions which allow transitions between neighboring eigenstates of  $\hat{M}_z$ , the states  $\hat{R}_{\text{maxent}}$  relax towards one or another of the dynamically stable states  $\hat{R}_{\lambda} = \lambda \hat{R}_{\uparrow} + (1-\lambda) \hat{R}_{\downarrow}$  ( $0 \leq \lambda \leq 1$ ), the value of  $\langle \hat{M}_z \rangle$  remaining nearly fixed. (This may be checked as an exercise by working out the ‘‘poly-microcanonical’’ relaxation mechanism [36].) Mathematically, the states  $\hat{R}_{\lambda}$ , including the pointer states  $\hat{R}_{\uparrow}$  and  $\hat{R}_{\downarrow}$ , are not rigorously stable and relax for finite  $N$  towards  $\hat{R}_{\text{eq}}$  (with  $\lambda = 1/2$ ), but extremely slowly. In fact, the relaxation time is exponentially large in  $N$  and all states  $\hat{R}_{\lambda}$  can physically be regarded as fully stable. More generally, for an arbitrary ideal measurement, the very long lifetime of the states  $\hat{R}_i$  allows the outcome  $A_i$  to be read not much later than the end  $t_f$  of the process.

<sup>19</sup> The quantities  $U_i$ ,  $S_i$  and  $Z_i = Z = \text{Tr} \exp[-(\hat{H}_M + \hat{h}_i)/T] = \exp(S_i - U_i/T)$  are the same for all  $i$ .

<sup>20</sup> Strictly speaking,  $\hat{\pi}_i$  acts in the Hilbert space  $\mathcal{H}_S$ . In such equations pertaining to the space  $\mathcal{H}$ ,  $\hat{\pi}_i$  is meant as  $\hat{\pi}_i \otimes \hat{I}_A$ , where  $\hat{I}_A$  is the unit operator in the space  $\mathcal{H}_A$ . Likewise, in § 4.3.1,  $\hat{x}_{\alpha}$  stands for  $\hat{x}_{\alpha} \otimes \hat{I}_M$ .

space  $\mathcal{H}_M$ <sup>21</sup>. In the special case when  $\hat{r}(0) = \hat{\pi}_i \hat{r}(0) \hat{\pi}_i$ , S is unaffected by the dynamics in the Schrödinger picture while M is governed by the effective Hamiltonian  $\hat{H}_M + \hat{K}_i$ . As we wish then the pointer to take the macroscopic value  $A_i$ , the operator  $\hat{K}_i$  should have the form of a source  $\hat{h}_i$  introduced in § 3.2.1 to define the state (7). Altogether, since  $\hat{\pi}_i \hat{H}_{SM} \hat{\pi}_j = 0$  for  $i \neq j$ , the interaction between S and M should have the form

$$\hat{H}_{SM} = \sum_i \hat{\pi}_i \otimes \hat{h}_i. \quad (10)$$

With such an interaction, we expect that, if  $\hat{r}(0) = \hat{\pi}_i \hat{r}(0) \hat{\pi}_i$ , M reaches at the end of the joint relaxation process of S+M the marginal state given by (7). If afterwards the coupling between S and M is switched off, and if  $\hat{h}_i$  is sufficiently small, we expect M to reach  $\hat{R}_i$  as in (8).

For instance, in the Curie-Weiss model of measurement, we saw in § 3.2.1 that the magnet M can be driven towards states close to the ferromagnetic states  $\hat{R}_\uparrow$  or  $\hat{R}_\downarrow$  by sources of the form  $\hat{h}_\uparrow = -g\hat{M}_z$  or  $\hat{h}_\downarrow = +g\hat{M}_z$ . Thus, if the tested spin S is coupled to M through  $\hat{H}_{SM} = \hat{\pi}_\uparrow \otimes \hat{h}_\uparrow + \hat{\pi}_\downarrow \otimes \hat{h}_\downarrow = -g\hat{s}_z \otimes \hat{M}_z$ , with a small but finite  $g$ , M is triggered by  $\hat{h}_\uparrow$  if S is oriented in the  $+z$ -direction, or by  $\hat{h}_\downarrow$  if S lies in the  $-z$ -direction. In case the initial paramagnetic state  $\hat{R}(0)$  is partly stabilized by a free energy barrier,  $g$  must be *large enough* to overcome this barrier and allow the relaxation towards one of the stable ferromagnetic states.

### 3.2.3. A non-perturbing measurement

As defined in § 1.1 and recalled in § 3.1, an ideal measurement requires M to *end up in the state  $\hat{R}_i$  if  $\hat{s}$  takes the value  $s_i$*  in the initial state  $\hat{r}(0)$  of S. We focus here on the dynamics of S + A for an initial state  $\hat{r}(0)$  of S satisfying  $\hat{r}(0) \equiv \hat{\pi}_i \hat{r}(0) \hat{\pi}_i$ , a case already considered in § 3.2.2 to construct  $\hat{H}_{SM}$ . (If the eigenvalue  $s_i$  of  $\hat{s}$  is non-degenerate,  $\hat{r}(0) = \hat{\pi}_i$ .) The solution of the Liouville–von Neumann equation (2) then behaves as  $\mathcal{D}(t) = \hat{r}(0) \otimes \mathcal{R}(t)$ , where

$$i\hbar \frac{d\hat{\mathcal{R}}(t)}{dt} = [\hat{H}_M + \hat{h}_i + \hat{H}_B + \hat{H}_{MB}, \hat{\mathcal{R}}(t)]. \quad (11)$$

In this special case, the system S remains unaffected and the coupling (10) has the sole effect of yielding the dynamical equation (11) for the apparatus. This equation is the same as if M+B were alone (§ 3.2.1), but with  $\hat{H}_M + \hat{h}_i$  as proper Hamiltonian of M, the operator  $\hat{h}_i$  issued from  $\hat{H}_{SM}$  behaving as a source that favours the outcome  $A_i$  as in § 3.2.1. The contributions  $\hat{H}_B + \hat{H}_{MB}$  of the bath are expected to drive the marginal state  $\hat{R}(t) = \text{tr}_B \hat{\mathcal{R}}(t)$  of M towards the equilibrium state (7)  $\hat{R}_i^h$  expressed by (7). Then, at the very end of the process, S and A can be separated,  $\hat{H}_{SM}$  is switched off. The measuring device M then evolves from  $\hat{R}_i^h$  to the neighbouring final state  $\hat{R}_i$  as in (8), leaving practically unchanged the indication  $A_i$  of the pointer.

## 4. RELAXATION FOR THE FULL SET OF RUNS

Any large set of isolated quantum systems is described by a well-defined density operator that evolves deterministically, according to (2). For ideal measurements, this idea applies to the large set  $\mathcal{E}$  of compound systems S+A. We now determine the change of their density operator  $\hat{\mathcal{D}}(t)$  between the initial and final times  $t_i = 0$  and  $t_f$  of the process.

### 4.1. Initial state and equations of motion

We have beforehand to assign to S+A, along the lines of § 2.3, a density operator  $\hat{\mathcal{D}}(0)$  which accounts for our knowledge of S+A at the initial time  $t = 0$  of the process. The tested system S is supposed to have been prepared earlier in a given state  $\hat{r}(0)$ , and the measuring device M in a “ready” *metastable* state  $\hat{R}_M(0)$  characterized by some

<sup>21</sup> Likewise,  $\hat{H}_S$  must have the form  $\hat{H}_S = \sum_i \varepsilon_i \hat{\pi}_i$ . Such a contribution  $\hat{H}_S$  to  $\hat{H}$  has the sole effect of multiplying the off-diagonal blocks  $\hat{\pi}_i \hat{\mathcal{D}}(t) \hat{\pi}_j$  by the phase factor  $\exp i(\varepsilon_j - \varepsilon_i)t/\hbar$ . As these blocks eventually disappear at  $t = t_f$ , we set  $\hat{H}_S = 0$ , in which case S evolves only through its coupling to A.

macroscopic data. The large bath B lies in the equilibrium state (6) at temperature  $T$ . (For instance, in the Curie–Weiss model, M is initially set at  $T > T_C$  in a paramagnetic state with  $\langle \hat{M}_z \rangle = 0$ .) The *initial* state of the compound system S+M+B is therefore<sup>22</sup>

$$\hat{\mathcal{D}}(0) = \hat{r}(0) \otimes \hat{\mathcal{R}}(0), \quad \hat{\mathcal{R}}(0) = \hat{R}_M(0) \otimes \hat{R}_B(0). \quad (12)$$

The subsequent *evolution* of S+A in the Hilbert space  $\mathcal{H}$  is governed by the Liouville–von Neumann equation (2) for the isolated system S+A, with

$$\hat{H} = \hat{H}_A + \sum_i \hat{\pi}_i \otimes \hat{h}_i, \quad \hat{H}_A = \hat{H}_M + \hat{H}_B + \hat{H}_{MB}. \quad (13)$$

This dynamical equation can be simplified by relying on the *conservation laws* which characterize ideal measurements (§ 3.2.2). The commutation relations  $[\hat{H}, \hat{\pi}_i] = 0$  allow us to split it into<sup>20</sup>

$$i\hbar \frac{d\hat{\pi}_i \hat{\mathcal{D}}(t) \hat{\pi}_j}{dt} = [\hat{H}_A, \hat{\pi}_i \hat{\mathcal{D}}(t) \hat{\pi}_j] + \hat{h}_i \times \hat{\pi}_i \hat{\mathcal{D}}(t) \hat{\pi}_j - \hat{\pi}_i \hat{\mathcal{D}}(t) \hat{\pi}_j \times \hat{h}_j. \quad (14)$$

The solution of (14) with the initial condition (12) has the form

$$\hat{\pi}_i \hat{\mathcal{D}}(t) \hat{\pi}_j = \hat{\pi}_i \hat{r}(0) \hat{\pi}_j \otimes \hat{\mathcal{R}}_{ij}(t), \quad (15)$$

where the operators  $\hat{\mathcal{R}}_{ij}(t)$  in the space  $\mathcal{H}_A$  are determined by

$$i\hbar \frac{d\hat{\mathcal{R}}_{ij}(t)}{dt} = [\hat{H}_A, \hat{\mathcal{R}}_{ij}(t)] + \hat{h}_i \hat{\mathcal{R}}_{ij}(t) - \hat{\mathcal{R}}_{ij}(t) \hat{h}_j, \quad (16)$$

with the initial conditions

$$\hat{\mathcal{R}}_{ij}(0) = \hat{R}_M(0) \otimes \hat{R}_B(0). \quad (17)$$

In the special case where  $\hat{r}(0) \equiv \hat{\pi}_i \hat{r}(0) \hat{\pi}_i$ , there is a single relevant block  $\hat{\mathcal{R}}_{ii}$  and we recover (11) for it.

Owing to the conservation laws which express ideality (§ 3.2.2), the equations of motion (15)–(17), associated with the separate sectors of S, involve *only the apparatus* A. The tested system S contributes only through the sources  $\hat{h}_i$  in the Hilbert space  $\mathcal{H}_M$ . Dynamics thus exhibit the major role played by the apparatus in an ideal measurement process.

## 4.2. Statistical mechanics approach

Explicit solutions of the equations (16) may be worked out for sufficiently simple models in courses of statistical mechanics, either as formal lectures or as illustrative exercises. An extensive review of such models is presented in [13], which also displays a detailed study of the Curie–Weiss model, including a discussion of the validity of various needed approximations.

We complement here such approaches with a few comments of tutorial interest. In Appendix A, we discuss the role of the bath and recall how, for a weak coupling  $\hat{H}_{MB}$ , in which case standard approximations of quantum statistical mechanics can be used, the equations (16) for A =M+B can further be reduced to equations for the *sole measuring device* M.

According to (16), *two independent types of evolution* of S+A *coexist* during an ideal measurement process, with *two different relaxation times*. Each *diagonal* block  $\hat{\mathcal{R}}_{ii}(t)$  obeys the same equation (11) as if  $\hat{s}$  took initially the value  $s_i$ , and it will thus end up as  $\hat{\mathcal{R}}_{ii}(t_f) = \hat{\mathcal{R}}_i$  characterized by (8). Owing to the *action* of S *on* M (implemented through a sufficiently large coupling factor  $\hat{h}_i$  in the interaction  $\hat{H}_{SM}$ ), this process establishes through (15) a *correspondence* within  $\hat{\mathcal{D}}(t_f)$  between the final macroscopic *indication*  $A_i$  of the pointer and the *eigenvalue*  $s_i$  of  $\hat{s}$ . We thus term it “*registration*” ([13], Sec. 7).

Each *off-diagonal block*  $\hat{\mathcal{R}}_{ij}(t)$  ( $i \neq j$ ) of  $\hat{\mathcal{D}}(t)$  decays and vanishes well before  $t = t_f$ . We term this disappearance “*truncation*” of the state  $\hat{\mathcal{D}}(t)$  of S+A. It arises from the non-Hamiltonian terms of (16) for  $i \neq j$ , which come out

<sup>22</sup> The product form of (12) can be derived (§ 2.3) by maximizing the entropy  $S[\hat{\mathcal{D}}(0)]$  and accounting for the constraints  $\text{tr}_A \hat{\mathcal{D}}(0) = \hat{r}(0)$ ,  $\text{tr}_B \hat{\mathcal{D}}(0) = \hat{R}_M(0)$ ,  $\text{tr}_{SM} \hat{\mathcal{D}}(0) = \hat{R}_B(0)$  through Lagrange multipliers.

because the action  $\hat{h}_i$  of S on M is not the same for the eigenvalues  $s_i$  and  $s_j$ . In return, the action of M on S results in the “reduction” of the marginal state  $\hat{r}(t) = \text{tr}_A \hat{D}(t) = \text{tr}_M D(t)$ , according to  $\hat{\pi}_i \hat{r}(t) \hat{\pi}_j = 0$  for  $i \neq j$ . Depending on the model, truncation may be achieved by different mechanisms (dephasing by the many degrees of freedom of M, or decoherence due to the coupling with B) of pedagogical interest, involving or not the bath ([13], Secs. 5 and 6).

As we shall see in § 5, this disappearance of the off-diagonal blocks, as usual in decoherence, is not sufficient to solve the measurement problem. Indeed, we cannot yet ascertain (§ 5.2) that each diagonal block is physically meaningful in terms of the outcomes of the pointer.

Simple illustrative exercises, where the bath is disregarded, are worked out in Appendix B. It is instructive to discover how the interaction of S with M, in a dynamical process designed to test the observable  $\hat{s}$ , *destroys the q-information* pertaining to the observables of S *incompatible with  $\hat{s}$* , initially embedded in the off-diagonal blocks of  $\hat{r}(0)$ . In appendix B.3, we also acknowledge how this irreversibility arises through a *cascade of q-correlations*.

In Appendix C, we analyze the features which allow us to overcome the *irreversibility paradox* in the dynamical study of measurement processes. It turns out that the very understanding of measurement theory requires the use of *approximations* which, however, become fully justified in the limit of large M and B (as in the paradox of irreversibility in statistical mechanics for a macroscopic piece of material).

### 4.3. Thermodynamic approach

The task is to show that the quantum dynamics brings us from the metastable to the stable states. This has been achieved in great detail in ref. [13]. We bypass here the solution of the above dynamical equations, and directly construct the final state  $\hat{D}(t_f) = \text{tr}_B \hat{D}(t_f)$  of S+M by relying on an argument which students should readily accept<sup>4</sup>. As in macroscopic thermodynamics, we admit that S+M, which is an open system weakly coupled to an infinitely large bath B, *relaxes towards thermodynamic equilibrium* at the temperature  $T$  of B. This property can be checked from (16) on models where the interactions are sufficiently intricate to irreversibly raise the entropy  $S[\hat{D}(t)]$  of S+M up to the largest value compatible with the conservation laws. The density operator provided by the *maximum entropy* criterion (§ 2.3) then appears not only as the *least biased* one [31–33], but also describes the *stable* equilibrium reached after relaxation [13].

#### 4.3.1. Equilibrium states of S+M

As a preliminary step, which may constitute an exercise of statistical mechanics, we determine the general form of the thermodynamic equilibrium states  $\hat{D}_{\text{eq}}$  of the system S+M weakly coupled to a thermal bath B. As indicated at the end of § 2.3, we first gather the *constraints* on  $\hat{D}$ . *Normalization* fixes  $\text{Tr}_{\text{SM}} \hat{D} = 1$ . The weak interaction of S+M with the bath fixes the *q-expectation* value  $\text{Tr}_{\text{SM}} \hat{D}(\hat{H}_M + \hat{H}_{\text{SM}})$  of its *energy*. Furthermore, the conserved quantities  $\hat{x}$  defined by (9) provide *constants of the motion* which result in constraints. These constraints are expressed as  $\text{Tr}_{\text{SM}} \hat{D} \hat{x}_\alpha = \langle \hat{x}_\alpha \rangle$  where we denote as  $\hat{x}_\alpha$  the elements of a basis of linearly independent operators in the vector space of observables  $\hat{x}$ . (For a non-degenerate spectrum of  $\hat{s}$ , the  $\hat{x}_\alpha$ ’s are the projectors  $\hat{\pi}_i$ .)

The resulting thermodynamic equilibrium state  $\hat{D}_{\text{eq}}$  is determined by looking for the maximum of the von Neumann entropy  $S(\hat{D}) = -\text{Tr} \hat{D} \ln \hat{D}$ , the above constraints being taken into account by means of Lagrange multipliers  $\gamma$ ,  $\beta$ , and  $\lambda_\alpha$ , respectively. The stationarity condition (13) then provides for  $\hat{D}_{\text{eq}}$  the *generalized canonical form*<sup>23</sup>

$$\ln \hat{D}_{\text{eq}} + \gamma \hat{I}_{\text{SM}} + \beta(\hat{H}_M + \hat{H}_{\text{SM}}) + \sum_{\alpha} \lambda_{\alpha} \hat{x}_{\alpha} = 0, \quad (18)$$

where  $\hat{H}_{\text{SM}} = \sum_i \hat{\pi}_i \otimes \hat{h}_i$  and where  $\hat{I}_{\text{SM}}$  is the identity operator in  $\mathcal{H}_S \otimes \mathcal{H}_M$ .

The explicit derivation of  $\hat{D}_{\text{eq}}$  from (18) may be taught as an algebraic exercise. The operator  $\hat{X} \equiv \beta(\hat{H}_M + \hat{H}_{\text{SM}}) + \gamma \hat{I}_{\text{SM}} + \sum_{\alpha} \lambda_{\alpha} \hat{x}_{\alpha}$  satisfies  $[\hat{\pi}_i, \hat{X}] = 0$  or  $\hat{\pi}_i \hat{X} \hat{\pi}_j = 0$  for  $i \neq j$ , which entails  $\hat{\pi}_i \hat{D}_{\text{eq}} \hat{\pi}_j = 0$  for  $i \neq j$ . The equality  $\hat{\pi}_i \ln \hat{D}_{\text{eq}} \hat{\pi}_i = -\hat{\pi}_i \hat{X}$  then provides

$$\hat{\pi}_i \hat{D}_{\text{eq}} \hat{\pi}_i = \hat{\pi}_i \exp(-\hat{\pi}_i \hat{X}) = \hat{\pi}_i \exp[-\hat{Y}], \quad \hat{Y} = \beta \hat{\pi}_i \otimes (\hat{H}_M + \hat{h}_i) + \gamma \hat{\pi}_i \otimes \hat{I}_M + \sum_{\alpha} \lambda_{\alpha} \hat{\pi}_i \hat{x}_{\alpha} \otimes \hat{I}_M,$$

<sup>23</sup> The inequality  $\text{Tr} \hat{D}(\ln \hat{D} - \ln \hat{D}_{\text{eq}}) > 0$ , valid for any  $\hat{D} (\neq \hat{D}_{\text{eq}})$  satisfying the same constraints as  $\hat{D}_{\text{eq}}$ , shows that this stationary value is a *maximum*. The result (18) may alternatively be found by looking for the maximum of the Massieu thermodynamic potential  $S(\hat{D}) - \beta \text{Tr}_{\text{SM}} \hat{D}(\hat{H}_M + \hat{H}_{\text{SM}})$  for given  $\text{tr}_{\text{SM}} \hat{D} \hat{x}_{\alpha}$ . Note that the constraints are overabundant, since they include the unit operator which is a linear combination of the  $\hat{x}_{\alpha}$ ’s (for instance, for a spin  $\frac{1}{2}$ :  $\hat{\pi}_{\uparrow} + \hat{\pi}_{\downarrow} = \hat{I}_2$ ).

from which we obtain

$$\hat{D}_{\text{eq}} = \sum_i \exp \left( - \sum_{\alpha} \lambda_{\alpha} \hat{\pi}_i \hat{x}_{\alpha} - \gamma \right) \otimes \exp \left[ -\beta(\hat{H}_M + \hat{h}_i) \right]. \quad (19)$$

In the space  $\mathcal{H}_M$ , for each  $i$ , the last factor provides (within normalization) the equilibrium state  $Z \times \hat{R}_i^h$  of Eq. (7) that M alone would reach at the bath temperature  $T = 1/\beta$  if its Hamiltonian were  $\hat{H}_M + \hat{h}_i$ . In the space  $\mathcal{H}_S$ , we reparametrize the first factor in terms of a scalar  $p_i$  and a normalized matrix  $\hat{r}_i$  as

$$Z \exp \left( - \sum_{\alpha} \lambda_{\alpha} \hat{\pi}_i \hat{x}_{\alpha} - \gamma \right) \equiv p_i \hat{r}_i, \quad (20)$$

where  $\hat{r}_i$  satisfies

$$\hat{r}_i \equiv \hat{\pi}_i \hat{r}_i \hat{\pi}_i, \quad \text{Tr}_S \hat{r}_i = 1. \quad (21)$$

Normalization of  $\hat{D}_{\text{eq}}$  implies  $\sum_i p_i = 1$ .

Altogether, the sought thermodynamic equilibrium states of S+M are found as a weighted sum

$$\hat{D}_{\text{eq}} = \sum_i p_i \hat{r}_i \otimes \hat{R}_i^h, \quad (22)$$

where  $\hat{r}_i$  behaves as a density operator confined in the subspace of  $\mathcal{H}_S$  spanned by  $\hat{\pi}_i$ . The  $\hat{r}_i$ 's and the  $p_i$ 's should be determined from data pertaining to S.

#### 4.3.2. The final state

Admitting that the final state  $\hat{D}(t_f)$  of S+M has the thermodynamic equilibrium form (22), we determine its parameters  $p_i$  and  $\hat{r}_i$  by relying on the existence (§ 3.2.2) of the constants of the motion  $\text{Tr}_{\text{SM}} \hat{D}(t) \hat{x}_{\alpha} = \langle \hat{x}_{\alpha} \rangle$ . During the dynamical process, they keep some memory of the initial state  $\hat{D}(0) = \hat{r}(0) \otimes \hat{R}_M(0)$ . As the conserved observables  $\hat{x}$  have the form (9), the identity of  $\text{Tr}_{\text{SM}} \hat{D}(t_f) \hat{x}$  and  $\text{Tr}_{\text{SM}} \hat{D}(0) \hat{x}$  yields

$$\text{Tr}_S \sum_j p_j \hat{r}_j \sum_i \hat{\pi}_i \hat{y} \hat{\pi}_i = \text{Tr}_S \hat{r}(0) \sum_i \hat{\pi}_i \hat{y} \hat{\pi}_i \quad (23)$$

for any operator  $\hat{y}$  of  $H_S$ . Using (21) and the arbitrariness of  $\hat{y}$ , we find<sup>24</sup>

$$p_i = \text{Tr}_S \hat{r}(0) \hat{\pi}_i, \quad (24)$$

$$\hat{r}_i = \frac{\hat{\pi}_i \hat{r}(0) \hat{\pi}_i}{\text{Tr}_S \hat{r}(0) \hat{\pi}_i}, \quad (25)$$

Thus, as long as  $\hat{H}_{\text{SM}}$  is switched on, S+M reaches the equilibrium state  $\hat{D}_{\text{eq}}(t)$  of Eqs. (22), (24), (25). We assumed in § 3.2.3 that, a little before the end of the process, the interaction  $\hat{H}_{\text{SM}}$  is switched off. Then, if the equilibrium states  $\hat{R}_i$  of M are well separated, the dynamical equation for the state  $\hat{R}(t) = \text{tr}_S \hat{D}(t)$  will lead  $\hat{R}(t)$  from  $\hat{R}_i^h$  given by (7) to  $\hat{R}_i$ , defined mathematically in § 3.2.1 as the limit for  $\hat{h}_i \rightarrow 0$  of  $\hat{R}_i^h$ .

Altogether, the set  $\mathcal{E}$  of compound systems S+M initially prepared in the state  $\hat{D}(0) = \hat{r}(0) \otimes \hat{R}_M(0)$  is represented, at the *final time*  $t_f$  of the process, by the density operator

$$\hat{D}(t_f) = \sum_i p_i \hat{D}_i, \quad \hat{D}_i \equiv \hat{r}_i \otimes \hat{R}_i. \quad (26)$$

The weights  $p_i$  and the operators  $\hat{r}_i$  keep partly track of the initial state  $\hat{r}(0)$  of the tested system S through (24), (25), while  $\hat{R}_i$  is characterized by the macroscopic pointer value (8). The bath is so large that it is practically unaffected

<sup>24</sup> Eq. (24) results from the conservation of  $\hat{\pi}_i$ . Eq. (25) reduces to  $\hat{r}_i = \hat{\pi}_i$  for a non-degenerate eigenvalue  $s_i$  of  $\hat{s}$ .

in spite of its perturbation through  $\hat{H}_{\text{MB}}$  and its change of free energy, so that the final state of S+M+B issued from (12) is

$$\hat{\mathcal{D}}(t_f) = \sum_i p_i \hat{r}_i \otimes \hat{R}_i \otimes \hat{R}_B(0). \quad (27)$$

This result encompasses everything we can tell within the quantum formalism about S+A at the time  $t_f$ , knowing the initial state and the dynamics. We cannot go further and give a physical meaning to the separate elements of (27) as long as the pointer indications are not read, as will be explained below (§ 5.2). However, this expression is the best possible quantum mechanical description *for the full set*  $\mathcal{E}$  of systems S+M+B at the time  $t_f$ . As regards the system S after separation from A, our knowledge of its final density operator  $\hat{r}(t_f) = \text{tr}_A \hat{\mathcal{D}}(t_f) = \sum_i p_i \hat{r}_i$  allows us to make predictions about further experiments performed on S, in case we do not observe the pointer and pick up at random the outcomes of the process.

## 5. THE MEASUREMENT PROBLEM REVISITED

According to the definition of a quantum state (§ 2.1.3), the final density operator  $\hat{\mathcal{D}}(t_f)$  of S+A describes *formally* the outcome of the *full set*  $\mathcal{E}$  of runs, for an initial state  $\hat{\mathcal{D}}(0)$  of S+A. *Physical interpretation* of  $\hat{\mathcal{D}}(t_f)$  requires, as already stressed and recalled below, to extract from this operator properties of *individual runs*. This is impeded by a purely quantum difficulty (§ 5.2), which we must overcome (§ 5.3).

### 5.1. Measurements and individual runs

Our purpose is to explain, by studying *ideal* measurements as a model, the following features of *real* experiments.

- Information about a measurement are generally obtained in the form of data  $A_i$  carried by the pointer of the apparatus. We focus on discrete data, defined within some resolution. In the ideal measurement model, these data  $A_i$  are associated, according to Eq. (3.4), with the specific states  $\hat{R}_i$  of M. A good resolution, such that their interval is large compared to the  $q$ -fluctuation of  $\hat{A}$ , requires a proper apparatus with a macroscopic pointer.
- Observation of the data  $A_i$  requires a safe registration by the apparatus during a sufficiently large delay. The ideal measurement model defined in § 3 readily satisfies this property. If reading or registration take place while S and A are still coupled,<sup>25</sup> it is ensured by the stability of the equilibrium state  $\hat{R}_i^h$  defined by (3.3). After separation of S from A, the state  $\hat{R}_i$  is not rigorously stable,<sup>18</sup> but its lifetime is extremely long, allowing ample time for reading off or registering the outcome.
- Among the large set of runs of a measurement<sup>13</sup>, the outcome of each one is observed individually, yielding a statistic of the possible values of  $A_i$ , and hence of the possible values of  $s_i$ .
- For a non-demolishing measurement, the selection of runs with a given outcome  $A_i$  constitutes a preparation of S in a new, collapsed state.

The last two *experimental* features are based on the occurrence of a definite answer, characterized by the final value  $A_i$  of the pointer variable for each individual process. In spite of the banality of this property, we have to explain it *theoretically*, by relying on our only knowledge, the initial state of S+A, and on quantum dynamics. Then, quantum theory provides nothing more than the result (27) for  $\hat{\mathcal{D}}(t_f)$ , which formally describes the outcome of the full set of runs but does not refer to such different *exclusive events* occurring in individual runs.

No problem arises in the special case when the initial state is pure,  $\hat{r}(0) = \hat{\pi}_i \hat{r}(0) \hat{\pi}_i = \hat{r}_i$ , lying in the eigenspace associated with the single eigenvalue  $s_i$ . Then, the theoretical approach of § 3.2.3 yields as final density operator  $\hat{\mathcal{D}}(t_f) = \hat{\mathcal{D}}_i$ . Consequently, as physically expected, the marginal states of M and S are found as  $\hat{R}_i$  and  $\hat{r}_i$ , respectively, implying that each individual run provides the pointer value  $A_i$ . Thus the state  $\hat{r}_i$  of S is left unchanged for any subset of runs.

However, for an arbitrary initial state  $\hat{r}(0)$  of S, we cannot a priori infer from  $\hat{\mathcal{D}}(t_f)$  that each run yields a definite indication  $A_i$  of the pointer. Nor can we split the expression (27) of  $\hat{\mathcal{D}}(t_f)$  into meaningful terms in spite of its

<sup>25</sup> For instance, in ref. [38], the reading-off is done as late as possible before decoupling.

suggestive form<sup>26</sup>. As will be shown in § 5.2, the *quantum principles alone* do not suffice to achieve these goals. It is impossible to derive from the sole knowledge of  $\hat{\mathcal{D}}(t_f)$  a physical interpretation for its elements  $p_i$  and  $\hat{r}_i$ . This measurement problem is a specifically quantum difficulty issued from Schrödinger's ambiguity.

## 5.2. Schrödinger's ambiguity

The above impossibility of directly giving a physical meaning to the separate terms of (27) arises from Schrödinger's *ambiguity of decompositions* of a non-pure density operator [13, 39] (also known as the impossibility of an ignorance-interpretation of mixtures). We saw in § 2.2.3 that the merger of two sets  $\mathcal{E}_1$  and  $\mathcal{E}_2$  of systems represented by density operators  $\hat{\mathcal{D}}_1$  and  $\hat{\mathcal{D}}_2$  produces a set  $\mathcal{E}$  described by a linear combination of  $\hat{\mathcal{D}}_1$  and  $\hat{\mathcal{D}}_2$  (Eq. (3)). Given conversely a density operator  $\hat{\mathcal{D}}$  describing a physical set  $\mathcal{E}$ , without any further information, consider a sum into which it can be decomposed,

$$\hat{\mathcal{D}} = \sum_k \lambda_k \hat{\mathcal{D}}_k, \quad (28)$$

where the operators  $\hat{\mathcal{D}}_k$  have the mathematical properties of density operators (§ 2.1.2) and where the weights  $\lambda_k$  are positive and normalized. (The final state (27) of S+A is such a sum.) The form of this expression suggests that the state  $\hat{\mathcal{D}}_k$  might represent some physical subset  $\mathcal{E}_k$  of  $\mathcal{E}$ . Nevertheless,  $\hat{\mathcal{D}}$  has also many other decompositions

$$\hat{\mathcal{D}} = \sum_j \mu_j \hat{\mathcal{D}}'_j, \quad (29)$$

which suggest that the state  $\hat{\mathcal{D}}'_j$  might represent some other subset  $\mathcal{E}'_j$  of  $\mathcal{E}$ . Then, we will show that one can always find pairs (28), (29) of *mathematical* decompositions such that a *contradiction* would arise if there existed *physical* subsets  $\mathcal{E}_k$  and  $\mathcal{E}'_j$  represented by  $\hat{\mathcal{D}}_k$  and  $\hat{\mathcal{D}}'_j$ . Hence, if no other information than  $\hat{\mathcal{D}}$  is available, the elements of its mathematical decompositions *cannot be interpreted as density operators associated with physical subsets of  $\mathcal{E}$* . A general proof is given in Appendix D, suited to be taught as exercises.

Let us demonstrate this point on a simple illustrative example. Consider an set  $\mathcal{E}$  of unpolarized spins  $\frac{1}{2}$  (or of fully random  $q$ -bits), described by the quantum state  $\hat{\mathcal{D}} = \frac{1}{2}\hat{I}$ . The operator  $\hat{\mathcal{D}} = \frac{1}{2}\hat{I}$  can be decomposed into an incoherent sum  $\hat{\mathcal{D}} = \frac{1}{2}(|+z\rangle\langle+z| + |-z\rangle\langle-z|)$  of two projectors associated with the orientations  $+z$  and  $-z$ , respectively. Alternatively,  $\hat{\mathcal{D}} = \frac{1}{2}\hat{I}$  can be decomposed into a sum  $\hat{\mathcal{D}} = \frac{1}{2}(|+x\rangle\langle+x| + |-x\rangle\langle-x|)$  involving the orientations  $+x$  and  $-x$ . If these mathematical decompositions of  $\hat{\mathcal{D}}$  were both physically meaningful, we would infer that  $\mathcal{E}$  might be split into two subsets  $\mathcal{E}_{+z}$  and  $\mathcal{E}_{-z}$  gathering individual spins polarized along  $+z$  and  $-z$ , respectively – but that it might also be split into two subsets  $\mathcal{E}_{+x}$  and  $\mathcal{E}_{-x}$  gathering spins polarized along  $+x$  and  $-x$ . Then, there would exist a subset  $\mathcal{E}_{+z} \cap \mathcal{E}_{+x}$  of  $\mathcal{E}$ , including a quarter of the spins, which would gather spins simultaneously polarized along  $+z$  and  $+x$ , which is absurd.

The ambiguity of mathematical decompositions of  $\hat{\mathcal{D}}$ , which forbids us to give them a physical meaning, occurs for any type of preparation, due to issues such as

- (a) *Lack of control* of some variables.
- (b) *Stochastic evolution*, such as depolarization.
- (c) *Merger*. Consider two sets  $\mathcal{E}_1^{(+z)}$  and  $\mathcal{E}_1^{(-z)}$  of systems made of spins  $\frac{1}{2}$  polarized in the pure states  $|+z\rangle$  and  $|-z\rangle$ , respectively. Somewhat artificially, we extract from them an equal number of individual systems, and gather them without keeping track of the ensemble they came from and forgetting the axis  $\pm z$  along which they had been polarized. The set  $\mathcal{E}_1$  resulting from this merger is described, according to (2.3), by the state  $\hat{\mathcal{D}}_1 = \frac{1}{2}(|+z\rangle\langle+z| + |-z\rangle\langle-z|) = \frac{1}{2}\hat{I}$ . Nothing else than  $\hat{\mathcal{D}}_1 = \frac{1}{2}\hat{I}$  is known about this set  $\mathcal{E}_1$ . A similar merger, starting from sets  $\mathcal{E}_2^{(+x)}$  and  $\mathcal{E}_2^{(-x)}$  such that the spins are polarized along  $\pm x$  instead of  $\pm z$ , produces a new set  $\mathcal{E}_2$  which is described by the state  $\hat{\mathcal{D}}_2 = \frac{1}{2}(|+x\rangle\langle+x| + |-x\rangle\langle-x|) = \frac{1}{2}\hat{I}$ . However, as  $\hat{\mathcal{D}}_1 = \hat{\mathcal{D}}_2 = \frac{1}{2}\hat{I}$ , no

<sup>26</sup> In the Curie-Weiss model, the initial state  $\hat{r}(0) = \hat{\pi}_\uparrow$  of S provides the final state  $\hat{\mathcal{D}}(t_f) = \hat{\mathcal{D}}_\uparrow = \hat{\pi}_\uparrow \otimes \hat{R}_\uparrow \otimes \hat{R}_B(0)$  of S+A for the full set, and also for any subset of runs, hence for individual runs. However, if the tested spin lies initially in the  $x$ -direction, we get  $\hat{\mathcal{D}}(t_f) = \frac{1}{2}(\hat{\mathcal{D}}_\uparrow + \hat{\mathcal{D}}_\downarrow)$  as final state for the full set of runs. Then, as indicated in<sup>18</sup>, all subsets are described by final states of the form  $\lambda\hat{\mathcal{D}}_\uparrow + (1-\lambda)\hat{\mathcal{D}}_\downarrow$  but the values of  $\lambda$  remain unknown. We cannot ascertain the existence of two complementary subsets with  $\lambda = 1$  and  $\lambda = 0$ . Nothing prevents us even, within the sole quantum formalism, from assigning the same density operator  $\frac{1}{2}(\hat{\mathcal{D}}_\uparrow + \hat{\mathcal{D}}_\downarrow)$  to any subset; then, the value of the pointer would be undetermined for any individual run.

experiment can distinguish the sets  $\mathcal{E}_1$  and  $\mathcal{E}_2$ . This impossibility of retrieving, in the quantum formalism, the physical difference between  $\mathcal{E}_1$  and  $\mathcal{E}_2$  arises from the *loss of the original information* about the direction of the polarization of each individual spin in the construction of these sets.

- (d) *Partial trace.* The difficulty is flagrant for a further set  $\mathcal{E}_3$  of unpolarized spins prepared by use of an *ancilla*, a second system. After having produced spin pairs in a singlet state, one extracts the first spin from each pair, disregarding the ancillary second spin (traced out as in § 2.2.2). The resulting set  $\mathcal{E}_3$  is again described by the state  $\hat{D}_3 = \frac{1}{2}\hat{I}$ , indistinguishable from  $\hat{D}_1$  and  $\hat{D}_2$ . Its preparation is isotropic, so that its discrete decompositions, which involves privileged directions, cannot be physically relevant.
- (e) *Approximate dynamics.* For a macroscopic system that relaxes to equilibrium, approximate methods of statistical mechanics (Appendix C) produce a final state which is mixed, therefore ambiguous. In measurements, the ambiguity of  $\hat{D}(t_f)$  is the result of such dynamics.

This ambiguity, a peculiarity of quantum descriptions (for non-pure states), has no equivalent for ordinary probabilities, which characterize the relative number of individual objects possessing some property [39]. There, each splitting of the probability distribution directly reflects a splitting of the considered physical set  $\mathcal{E}$  (which is then an ordinary statistical ensemble) into subsets (see end of Appendix D). In quantum mechanics, however, the matrix nature of “states”, which arises from the non-commutation of observables, precludes the existence of a physical subset of  $\mathcal{E}$  that would be described by a quantum formal entity such as  $\hat{D}_k$  in (28). As already stressed, a density operator is an abstract object that only refers to an *overall set* of systems, *not to a sample space* made of individual systems; it *cannot be split* into physically significant parts if nothing else is known.

### 5.3. A postulate concerning exclusive events

The measurement problem arises from the discrepancy between the expected physical features of individual ideal measurements (§ 5.1) and the abstract quantum description of the large set  $\mathcal{E}$  of systems S+M by the density matrix  $\hat{D} = \text{tr}_B \hat{D}$ . Knowing only the density operator  $\hat{D}(t_f)$  issued from  $\hat{D}(0)$  and expressed by (26), we are unable to extract information about individual runs. Indeed, due to the above ambiguity (§ 5.2), we cannot directly assert that the ingredients  $\hat{D}_i$  of its decomposition  $\hat{D}(t_f) = \sum_i p_i \hat{D}_i$  describe subsets, although this looks tempting – and will turn out to be correct. Students should be warned that more information than encoded in  $\hat{D}(t_f)$  is needed to overcome its ambiguity [39].

To deal with this difficulty, we acknowledge the existence of systems “M” having the following property  $\mathbb{P}$  inferred from macroscopic experience:

- $\mathbb{P}$ : A physical system “M” is an object which possesses several possible equilibrium states  $i$  characterized by the value  $A_i$  of some quantity, and which, under the considered conditions of preparation, reaches either one or another among them at the issue of each individual run of the experiment. We postulate that, not only a large set of such systems M, but also each of its large subsets distinguished by the value  $A_i$ , can be described in quantum theory by a density operator.

Examples of systems M are provided in statistical physics by materials with broken invariance, the variable  $A_i$  being the order parameter. For instance, the Ising magnet of § 3.2.1 has the required two equilibrium states  $\hat{R}_\uparrow$  and  $\hat{R}_\downarrow$  characterized by well-defined magnetizations  $+M_F$  or  $-M_F$ . The material reaches only one of these two states in individual experiments, in spite of the existence of many other equilibrium states<sup>18</sup> which are not produced in the considered situation.<sup>27</sup>

A measuring device should be a physical system M satisfying the above property  $\mathbb{P}$ . We thus acknowledge the existence of a pointer which gives a *well-defined indication*  $A_i$  at the issue of each *individual process*, allowing us to tag the runs by  $A_i$  at the time  $t_f$ . Hence, the set  $\mathcal{E}$  of systems S+M tested by the ideal measurement can be split (at the time  $t_f$ ) into subsets  $\mathcal{E}_i$ , termed as “*homogeneous*”, which gather all events having yielded the outcome  $A_i$ . Reading or registering these outcomes after achievement of the process requires *stability*, which is ensured by a *macroscopic* size of the apparatus.

<sup>27</sup> The role of the preparation of M in the postulate  $\mathbb{P}$  may be exemplified by superconductivity. Breaking in Fock space the invariance under transformations  $\exp(i\chi\hat{N})$ , where the particle number operator  $\hat{N}$  behaves as a quantum variable, leads theoretically to the BCS equilibrium states  $|\Psi_\phi\rangle$  characterized by an order parameter, the phase  $\phi$  of the pairing function  $\langle\psi_{\mathbf{k}\uparrow}\psi_{-\mathbf{k}\downarrow}\rangle$  (defined within  $2\pi$ ). If the superconducting sample M is part of a much larger system, this breaking of invariance is effective: the system reaches an equilibrium BCS state, an eigenstate of a unitary operator  $\exp(i\phi)$ , with a phase  $\phi$  taking well-defined values (within  $2\pi$ ) for individual samples. (More precisely, in superconducting devices, the well-defined quantities are the phase differences between different subsystems.) The phase  $\phi$  can be identified with the variable  $A_i$  of  $\mathbb{P}$ . However, if the system is produced with a given particle number  $N_0$ , pairing is theoretically taken into account by first breaking the invariance in Fock space, then by restoring it through projection on the Hilbert space for  $N_0$  particles. The equilibrium state is then proportional to  $\int_0^{2\pi} d\phi |\Psi_\phi\rangle \exp(-iN_0\phi)$ . The phase cannot be defined for individual runs and the property  $\mathbb{P}$  fails. (A similar restoration of broken invariance is currently used to account for pairing in nuclei.)

The postulate  $\mathbb{P}$  may be regarded as an implementation of the *Heisenberg cut*, a theoretical feature of ideal quantum measurements. Here, a kind of “cut” occurs between § 4 and § 5. On the first side (§ 4.2), we describe mathematically the ensemble  $\mathcal{E}$  of isolated systems S+A, between the times  $t = 0$  and  $t_f$ , by a density operator that evolves according to the Liouville–von Neumann equation, in the limit of a large A. On the second side (§ 5.3), a partly classical behavior is exhibited at the final time  $t_f$  for the pointer observable  $\hat{A}$ , as it takes for each individual run, at the issue of the process, a value  $A_i$  well-defined at the macroscopic scale, which can thereafter be read by an observer. This property, foreign to standard quantum mechanics which deals with ensembles, affords the required distinction of the subsets  $\mathcal{E}_i$  of  $\mathcal{E}$ .

*Physically*, the possible indications  $A_i$  are *exclusive*, so that the occurrence of some value  $A_i$  for each individual run appears as a probabilistic event. *Ordinary probabilities* in the sense of relative frequencies come out by counting those which yield each possible result. Thus, as regards the outcomes  $A_i$ , the set of runs constitute a *statistical ensemble* (§ 2.1.2). However, *theoretically* we have stressed that such physical features are foreign to the abstract quantum formalism of § 2, from which they cannot be deduced since quantum states refer only to sets. We will match this formalism with ordinary probability theory, which refers to *individual systems*, by incorporating the postulate  $\mathbb{P}$  into measurement theory.

To this aim, we note that, owing to the last part of this postulate, each homogeneous subset  $\mathcal{E}_i$  of systems S+M can be described at the time  $t_f$  by some density operator  $\hat{\Delta}_i$ . It now remains to determine  $\hat{\Delta}_i$  from the available data.

#### 5.4. Density operators of subsets

A rigorous assignment of a density operator  $\hat{\Delta}_i$  to each homogeneous subset  $\mathcal{E}_i$  of systems S+M after the time  $t_f$  will rely on two pieces of information (§ 2.3).

On the one hand, after the above property  $\mathbb{P}$  has allowed us to *distinguish* the subsets  $\mathcal{E}_i$  within  $\mathcal{E}$ , their merger must reconstruct the whole set  $\mathcal{E}$ , according to (3). We know that  $\mathcal{E}$  is represented at the time  $t_f$  by the density operator (26). Matching at  $t_f$  the quantum descriptions of the sets  $\mathcal{E}_i$  and  $\mathcal{E}$  yields a *constraint on the operators*  $\hat{\Delta}_i$ ,

$$\sum_i \mathcal{N}_i \hat{\Delta}_i = \mathcal{N} \hat{D}(t_f) = \mathcal{N} \sum_i p_i \hat{r}_i \otimes \hat{R}_i, \quad (30)$$

where  $\mathcal{N}_i$  (still to be determined) and  $\mathcal{N}$  are the respective numbers of runs of  $\mathcal{E}_i$  and  $\mathcal{E}$ . Due to the ambiguity of the decompositions of  $\hat{D}(t_f)$ , we are not yet allowed to infer from (5.3) that  $\mathcal{N}_i \hat{\Delta}_i = \mathcal{N} p_i \hat{r}_i \otimes \hat{R}_i$ .

On the other hand, each subset  $\mathcal{E}_i$  is characterized by the macroscopic value  $A_i$  of the pointer (§ 3.2.1). We wish to express this property as a mathematical constraint on  $\hat{\Delta}_i$ . In the Hilbert space  $\mathcal{H}_M$ , we extract from the spectrum of  $\hat{A}$  the eigenvalues lying between  $A_i - \delta$  and  $A_i + \delta$ , where  $\delta$  is much larger than the  $q$ -fluctuation of  $\hat{A}$  in  $\hat{R}_i$  and much smaller than the separations between the  $A_i$ 's. We denote as  $\hat{\Pi}_i$  the projector<sup>28</sup> on the subspace spanned by the corresponding eigenvectors of  $\hat{A}$ . The observable  $\hat{\Pi}_i$  characterizes the occurrence of the macroscopic indication  $A_i$ . This event occurs with certainty in the subset  $\mathcal{E}_i$ , so that (§ 2.1.4) the state  $\hat{\Delta}_i$  is constrained by  $\text{Tr} \hat{\Delta}_i \hat{\Pi}_i = 1$  in the Hilbert space  $\mathcal{H}_{SM}$ . Owing to the properties of density operators (§ 2.1.2), this property is equivalent to

$$\hat{\Pi}_i \hat{\Delta}_j \hat{\Pi}_i = \hat{\Delta}_i \delta_{ij}. \quad (31)$$

We have likewise

$$\hat{\Pi}_i \hat{R}_j \hat{\Pi}_i = \hat{R}_i \delta_{ij}. \quad (32)$$

Multiplying then (30) on the left and on the right side by  $\hat{I}_S \otimes \hat{\Pi}_i$  and making use of (31) and (32), we find

$$\mathcal{N}_i \hat{\Delta}_i = \mathcal{N} p_i \hat{r}_i \otimes \hat{R}_i. \quad (33)$$

This result agrees with a naive guess from (26), but both properties (30) and (31) have been needed to prove it.

Altogether, we have found the density operator  $\hat{\Delta}_i$  of S+A after the time  $t_f$  for the homogeneous subset  $\mathcal{E}_i$  as

$$\hat{\Delta}_i = \hat{D}_i = \hat{r}_i \otimes \hat{R}_i, \quad (34)$$

<sup>28</sup> The projectors  $\hat{\pi}_i$ , associated with  $s_i$  in the Hilbert space  $\mathcal{H}_S$ , and  $\hat{\Pi}_i$ , associated with  $A_i$  in the space  $\mathcal{H}_M$ , are in one-to-one correspondence but have different properties. The dimension of  $\hat{\Pi}_i$  is large as an exponential of the degrees of freedom of M, of order  $\exp S(R_i)$ . While  $\sum_i \hat{\pi}_i = \hat{I}_S$ , the sum  $\sum_i \hat{\Pi}_i$  spans only a subspace of  $\mathcal{H}_M$ . While  $\sum_i s_i \hat{\pi}_i = \hat{s}$ , the sum  $\sum_i A_i \hat{\Pi}_i$  does not encompass the full observable  $\hat{A}$ . While in an ideal measurement each  $\hat{\pi}_i$  is a constant of the motion ( $[\hat{\pi}_i, \hat{H}] = 0$ ),  $\hat{\Pi}_i$  cannot commute with  $\hat{H}$  since the pointer evolves between  $t = 0$  and  $t_f$  (under the effect of  $\hat{H}_{MB}$ ).

and the number  $\mathcal{N}_i$  of runs of  $\mathcal{E}_i$  as

$$\frac{\mathcal{N}_i}{\mathcal{N}} = p_i. \quad (35)$$

Through the expressions (24) and (25) of  $p_i$  and  $\hat{r}_i$ , these equations exhibit how the compound system S+M retains, after selection of the pointer indications, a partial memory of the initially prepared state  $\hat{r}(0)$  of S.

## 6. INTERPRETATION AND DISCUSSION

### 6.1. Macroscopic features and consistency

Although the quantum formalism does not describe individual systems, their consideration in the property  $\mathbb{P}$  of § 5.3 has allowed to introduce the subsets  $\mathcal{E}_i$  of  $\mathcal{E}$ , which could thereafter be represented by the quantum states  $\hat{D}_i$  of (34).

The above analysis shows how the postulate  $\mathbb{P}$ , issued from pre-quantum physics, can be conciliated with the quantum formalism – although explaining it would require new ideas. It leads, in the sense of § 6.5 (c) below, to a physical interpretation of some quantum quantities. Indeed, this property introduces within quantum mechanics a classical probabilistic structure for the outcomes  $A_i$  which constitute a standard sample space of probabilistic events. Thus, the *abstract q-probability*

$$p_i = \text{Tr}_{\text{SM}} \hat{D}(t_f) \hat{\Pi}_i \quad (36)$$

is identified through (35) with a *relative frequency*  $\mathcal{N}_i/\mathcal{N}$ , and is thus interpreted as the *ordinary probability of occurrence, within a large set of runs, of the outcome  $A_i$  for M*. The formal *q-expectation*  $\text{Tr}_{\text{SM}} \hat{D}(t_f) \hat{A} = \sum_i \mathcal{N}_i A_i / \mathcal{N}$  is interpreted as a *physical mean value*.

This interpretation holds *only after the time  $t_f$*  when thermodynamic equilibrium of S+M has been reached. Note also that *further decompositions* of the density operator  $\hat{D}_i$  associated with the subset  $\mathcal{E}_i$  would be plagued by Schrödinger's ambiguity and remain meaningless [39].

The possibility of reading, registering and selecting the pointer outcomes requires the states  $\hat{D}(t_f)$  and  $\hat{D}_i$  to be *stable*, not only as maximum entropy states, but *also dynamically* for slight shifts off equilibrium [13]<sup>18</sup>. This theoretical requirement is also consistent with the fact that a further measurement performed on an element of  $\mathcal{E}_i$  yields the result  $A_i$ .

### 6.2. Physical meaning of Born's rule

The above interpretation of (36) still refers only to the *apparatus*. The one-to-one correspondence between  $A_i$  and  $s_i$  exhibited in  $\hat{D}_i = \hat{r}_i \otimes \hat{R}_i$ , together with  $\text{Tr}_{\text{M}} \hat{R}_j \hat{\Pi}_i = \text{Tr}_{\text{S}} \hat{r}_j \hat{\pi}_i = \delta_{ij}$ , provides an alternative expression for  $p_i$ ,

$$p_i = \text{Tr}_{\text{SM}} \hat{D}(t_f) \hat{\pi}_i = \text{Tr}_{\text{S}} \hat{r}(t_f) \hat{\pi}_i, \quad (37)$$

which now refers to the *tested system*<sup>28</sup>. Observing the pointer yields *indirect* information about S. We can assert that, at the issue of the measurement process,  $\hat{s}$  takes the value  $s_i$  for each *individual run* tagged by the outcome  $A_i$ , and that  $p_i$  is the relative number of occurrences of the value  $s_i$  of the tested observable  $\hat{s}$  of S. *For the observable  $\hat{s}$*  (and for functions of  $\hat{s}$ ), *q-probabilities, q-expectation values, q-variances or q-correlations* (if  $\hat{s}$  is the product of two commuting observables) are thereby identified with ordinary probabilities, mean values, variances or correlations. However, this interpretation which requires a previous interaction with the dedicated macroscopic apparatus) is *restricted* to the *final equilibrium state* and to the *tested observable  $\hat{s}$* .

A third expression of  $p_i$  results from the dynamical treatment of the measurement process. Conservation of  $\hat{s}$ , expressed by  $[\hat{H}, \hat{\pi}_i] = 0$  (while  $\hat{\Pi}_i$  is not conserved), implies that  $\text{Tr}_{\text{SM}} \hat{D}(t) \hat{\pi}_i$  does not depend on time, and we get from (37)

$$p_i = \text{Tr}_{\text{SM}} \hat{D}(0) \hat{\pi}_i = \text{Tr}_{\text{S}} \hat{r}(0) \hat{\pi}_i. \quad (38)$$

By tracing out the apparatus, we have recovered the *standard form of Born's rule*:

$$p_i = \text{Tr}_{\text{S}} \hat{r}(0) \hat{\pi}_i, \quad \langle \hat{s} \rangle = \sum_i p_i s_i = \text{Tr}_{\text{S}} \hat{r}(0) \hat{s}. \quad (39)$$

Students should not be misled by the expressions (39), which involve *only S before interaction with A*, and which may suggest a physical interpretation of  $p_i$  in terms of the *sole initial state*  $\hat{r}(0)$  of S. But, rather, they are a result of a *dynamical conservation law* of  $\hat{s}$ , the presence of which is one of the conditions for ideality of the measurement. Moreover, the commutation of a state  $\hat{\rho}(0)$  with the set of projectors  $\hat{\pi}_i$  associated with the eigenvalues  $s_i$  of  $\hat{s}$  would be needed to interpret the occurrences of  $s_i$  as events of a probabilistic sample space (§ 2.1.4). As  $\hat{r}(0)$  *does not commute* in general with the observables  $\hat{\pi}_i$ , Born's  $q$ -probability  $\text{Tr}_S \hat{r}(0)\hat{\pi}_i$  *cannot be regarded, at the time*  $t = 0$ , *as a probability* in the sense  $p_i = N_i/N$ . This confirms that we should regard the “state”  $\hat{r}(0)$  as an abstract *mathematical tool* for making probabilistic predictions about the set of runs of any future experiment. However, while  $p_i$  can be interpreted as a probability of occurrence of the eigenvalue  $s_i$  at the *final time*  $t_f$ , one should not forget that, although the apparatus does not appear in its expression  $p_i = \text{Tr}_S \hat{r}(0)\hat{\pi}_i$ , this formula is an indirect consequence of the ordinary probabilities  $p_i = \text{Tr}_{SM} \hat{D}(t_f)\hat{\Pi}_i = \text{Tr}_M \hat{R}(t_f)\hat{\Pi}_i$  of *readings of the macroscopic pointer*.

In fact, (39) is the result of a *double inference*, first from M to S at the final time  $t_f$ , then from  $t_f$  to the initial time  $t_i = 0$ . The experimental determination from M of the frequencies  $p_i$  at  $t_f$  allows a partial retrodiction, yielding abstract  $q$ -information on  $\hat{r}(0)$  through (39).

### 6.3. Physical meaning of von Neumann's reduction

We have termed as *truncation* the disappearance of the off-diagonal blocks  $\hat{R}_{ij}(t)$  ( $i \neq j$ ) of the density matrix  $\hat{D}(t)$  of S+A (§ 4. 2). While being approximate, this disappearance is effective for all practical purposes. This was a necessary condition for splitting  $\hat{D}(t_f)$  into components describing the subsets  $\mathcal{E}_i$  of  $\mathcal{E}$ . The resulting change of state of the tested system S is called as usual *reduction* or *collapse*.

We now focus on the marginal state  $\hat{r}(t) = \text{tr}_M \hat{D}(t)$  of the tested system S. For the full set  $\mathcal{E}$  of runs, the ideal measurement of  $\hat{s}$  leads irreversibly  $\hat{r}(t)$  from  $\hat{r}(0)$  to

$$\hat{r}(t_f) = \text{tr}_A \hat{D}(t_f) = \sum_i \hat{\pi}_i \hat{r}(0) \hat{\pi}_i = \sum_i p_i \hat{r}_i. \quad (40)$$

This state is the one which should be assigned to S at the issue of the measurement *if the pointer is not read off* and if, accordingly, systems could not have been selected within  $\mathcal{E}$ . During the process, S has been perturbed by its interaction with A, which has eliminated the off-diagonal blocks  $\hat{\pi}_i \hat{r}(0) \hat{\pi}_j$  ( $i \neq j$ ) of  $\hat{r}(0)$ . Their disappearance represents a *loss of  $q$ -information* about observables that do not commute with  $\hat{s}$ , which is measured by  $S[\hat{r}(t_f)] - S[\hat{r}(0)]$ . This is a *price paid to acquire information about  $\hat{s}$*  [36].<sup>29</sup> Note that the entropy  $S[D(t)]$  of the compound system S+A increases due to its relaxation towards equilibrium.

For each subset  $\mathcal{E}_i$  of  $\mathcal{E}$ , the density operator to be assigned to S after the time  $t_f$  owing to the reading of the outcome  $A_i$  is given by (25) as

$$\hat{r}_i = \frac{\hat{\pi}_i \hat{r}(0) \hat{\pi}_i}{\text{Tr}_S \hat{r}(0) \hat{\pi}_i}. \quad (41)$$

We thus retrieve *von Neumann's reduction*, which comes out as the result of three steps: (i) *joint evolution of S+A* (§ 4); (ii) *selection of the runs* tagged at  $t_f$  by the value  $A_i$  of the pointer (§ 5.3); (iii) *elimination* of the measurement apparatus M.

The occurrence, for the same object S, of different final states  $\hat{r}(t_f)$  and  $\hat{r}_i$  under the same initial conditions illustrates the interpretation of a density operator as a catalogue of knowledge of the  $q$ -probabilities associated with a given set  $\mathcal{E}$  of systems<sup>7</sup> (§ 2.1.3). Knowing only that S has interacted with an apparatus devoted to the measurement of  $\hat{s}$  leads to the assignment of the state  $\hat{r}(t_f)$  to S. Learning moreover that the outcome  $A_i$  has been found leads to the assignment of  $\hat{r}_i$  for the accordingly selected set.

The so-called “*collapse*” leading  $\hat{r}(0)$  to some given  $\hat{r}_i$  may look paradoxical if one misinterprets it as a physical modification of an *individual* system S caused by its interaction with M. Of course, we acknowledge that each *individual physical process* leads to one among several different possible outcomes; but this property is not theoretically accounted for *in the quantum formalism* which only deals with sets. Before selection of the runs according to the indications of the pointer, the “state”  $\hat{r}(t)$  is an *indivisible* abstract description of the evolution of S for the *full set*  $\mathcal{E}$ , whereas each  $\hat{r}_i$  describes *after*  $t_f$  one among its homogeneous *subsets*  $\mathcal{E}_i$ , which were embedded beforehand within  $\mathcal{E}$ . The authors think that there is no sense in trying to explain within the standard quantum formalism the transition from the single

<sup>29</sup> Measuring the component  $\hat{s}_z$  of a spin destroys the information about  $\hat{s}_x$  and  $\hat{s}_y$  embedded in  $\hat{r}(0)$  in such a way that  $\langle \hat{s}_x \rangle = \langle \hat{s}_y \rangle = 0$  in the state  $\hat{r}(t_f)$ , a property which can be checked by subsequent ideal measurements of  $\hat{s}_x$  and  $\hat{s}_y$ .

state  $\hat{r}(0)$  of S to one among the states  $\hat{r}_i$  as some quantum process that would involve a “*bifurcation*” in the dynamics of S+A. In fact, quantum dynamics lead the whole set  $\mathcal{E}$  of systems S+A from the state  $\mathcal{R}(0)$  to  $\sum_i p_i \mathcal{R}_i$ , meaning that the sole knowledge of the initial state and of the interaction of S with A does not inform us about the state  $\hat{r}_i$  in which a given system S ends up. The “collapse” from  $\hat{r}(t_f)$  to  $\hat{r}_i$  is *not a physical process*. It results from a selection of the subset  $\mathcal{E}_i$ , which, grace to the postulate  $\mathbb{P}$ , can be described theoretically by  $\hat{r}_i$ .

Regarding a density operator as a means of prediction, von Neumann’s reduction is understood as an *updating of the  $q$ -information* on S, each subset  $\mathcal{E}_i$  being described by  $\hat{r}_i$  which encodes a new set of  $q$ -probabilities. This selection amounts to a *preparation* (§ 2.3) of the new quantum state  $\hat{r}_i$  of S. Reading the values  $A_i$  of the pointer provides us, on average, with an amount of  $q$ -information on S measured by  $S[\hat{r}(t_f)] - \sum_i p_i S(\hat{r}_i)$ .

If the eigenvalue  $s_i$  is non-degenerate, reduction prepares S in the pure state  $\hat{r}_i = \hat{\pi}_i$  whatever  $\hat{r}(0)$  (provided  $p_i \neq 0$ ). For a degenerate  $s_i$ , the reduced state (41) found above, which keeps some memory of the initial state  $\hat{r}(0)$  of S, is the one given by *Lüders’s rule* [40]. However, if this initial state is unknown, and if the result  $A_i$  has been read, we should assign to S at the time  $t_f$  the most random density operator compatible with the selected eigenvalue  $s_i$  of  $\hat{s}$  (§ 3.2.2). The above dynamical process for S+A followed by selection of the outcome  $A_i$  then produces an alternative reduced state given by *von Neumann’s rule*  $\hat{r}_i \propto \hat{\pi}_i$ .

This interpretation, based on the consideration of subsets determined by the indications of the apparatus, helps to understand EPR experiments. The system S is a pair of spins  $S'$  and  $S''$  first entangled in the singlet state  $\hat{r}(0)$  then sent far from each other, in regions  $X'$  and  $X''$  of space. The observable  $\hat{s}'_z = \hat{\pi}'_{\uparrow} - \hat{\pi}'_{\downarrow}$  is measured in the region  $X'$  with an apparatus  $M'$  coupled only to  $S'$ . If Alice observes for some run the outcome  $A'_{\uparrow}$  of the pointer at the time  $t_f$ , she is led to assign to S the reduced state  $\hat{r}' = \hat{\pi}'_{\uparrow} \otimes \hat{\pi}''_{\downarrow}$ . Hence, owing to the conservation of  $\hat{s}'_z + \hat{s}''_z$  she can *infer* that the spin  $S''$  located in the distant region  $X''$  lies in the marginal state  $\hat{r}''(t_f) = \hat{\pi}''_{\downarrow}$ . However, although entanglement allows Alice to get instantaneously knowledge at a distance about  $S''$ , there is no quantum communication at a distance. Indeed, before he communicates with Alice, Bob cannot do better than assigning to the spin  $S''$  an unpolarized marginal state; he can assign to  $S''$  the state  $\hat{r}''(t_f)$ , in view of performing subsequent experiments in the region  $X''$ , only *after Alice has transferred him*, from the region  $X'$  towards  $X''$ , the (*classical*) *information* that she acquired by having read the result  $A'_{\uparrow}$ .

#### 6.4. “Contextuality”: interpretation of measurement arises via the apparatus

Even though the standard properties (39) and (41) of ideal measurements are expressed in terms of S alone, we have exhibited the crucial role played by the apparatus A. To establish them theoretically, we relied on the equations of motion (16) which involve *only* A. To solve the measurement problem, we took advantage of the *uniqueness*  $\mathbb{P}$  of the pointer outcomes (§ 5.3), a property of a suitable macroscopic apparatus M.

This enforces the idea (§ 2.1.3) that the quantum “state”  $\hat{r}(0)$  of S can be regarded as a *synthesis of predictions* about experiments in which S interacts with *any possible external* apparatus, or “context”.<sup>30</sup> The full  $q$ -information embedded in  $\hat{r}(0)$  is latent, and only its part that pertains to the *specific observable*  $\hat{s}$  is unveiled in the form of ordinary, usable information, at the issue of the interaction of S with a *dedicated apparatus* A.

The joint measurement of non-commuting observables is an important question, still partly open, both experimentally and theoretically<sup>31</sup>. There, the above interpretation issued from the consideration of the outcomes of ideal measurements cannot be given, because *different apparatuses* acting on *different samples* would be required (§ 2.1.4). However, the situation is simple for *two commuting* observables  $\hat{s}'$  and  $\hat{s}''$ . The eigen-projectors  $\hat{\pi}'_j$  ( $j = 1, 2, \dots$ ) of  $\hat{s}'$  and  $\hat{\pi}''_k$  ( $k = 1, 2, \dots$ ) of  $\hat{s}''$  commute with each other, hence can simultaneously take the values  $\hat{\pi}'_j = 1$  and  $\hat{\pi}''_k = 1$ . This occurrence defines exclusive events  $(j, k)$  which constitute a sample space of probability theory. One can then associate with a state  $\hat{r}(0)$  of the system

*rmS* an ordinary probability distribution  $P(j, k) = \text{Tr}_S \hat{r}(0) \hat{\pi}'_j \hat{\pi}''_k$  where  $P(j, k)$  is the joint probability of occurrence of the eigenvalues  $s'_j$  for  $\hat{s}'$  and  $s''_k$  for  $\hat{s}''$ . Born’s expression  $\langle \hat{s}' \hat{s}'' \rangle = \text{Tr}_S \hat{r}(0) \hat{s}' \hat{s}''$  yields ordinary correlations  $\langle \hat{s}' \hat{s}'' \rangle - \langle \hat{s}' \rangle \langle \hat{s}'' \rangle$ . They can physically be determined by means of an ideal measurement performed with a compound apparatus measuring both  $\hat{s}'$  and  $\hat{s}''$ .

<sup>30</sup> This idea underlies the CSM approach [41, 42] which appears as a reverse of the present approach. Instead of being postulated as in § 2, the quantum formalism is constructed by starting from the consideration of “Modalities” M, which are exclusive events as in § 5.3. They involve, together with the “System” S, an infinite “Context” C, which is an idealization of the pointer of an apparatus and which is in correspondence with a basis of  $\mathcal{H}_S$ . A modality gathers a pure state of S and an associated value  $A_i$  of a classical variable of C, somewhat like our state  $\hat{D}_i = \hat{r}_i \otimes \hat{R}_i$ . Each given context generates ordinary probabilities  $p_i$ . However, the probabilistic structures generated by all possible different contexts are not compatible with an overall probability distribution. Nevertheless, by use of a construction based on Gleason’s theorem, that whole set of probabilities can be synthetically encoded in a density matrix for S, probabilities  $p_i$  being given by Born’s rule.

<sup>31</sup> Partial information about non-commuting observables may, however, simultaneously be gained through non-ideal measurements, as shown by solvable models (see § 8.3 of [13] and [43, 44]). Joint measurement of non-commuting observables raises experimental and theoretical questions.

Nevertheless, by putting together ordinary correlations determined by ideal measurements on  $\hat{r}(0)$  that require different experimental settings, one may stumble on results that seem *physically* (Bell [26]) or *logically* (GHZ [29]) incompatible. Consider for instance, as in the end of § 6.3, pairs of spins  $S'$  and  $S''$  previously prepared in the entangled singlet state  $\hat{r}(0)$ . We focus on the observables  $\hat{s}'_z, \hat{s}'_x, \hat{s}''_u, \hat{s}''_v$  referring to the directions  $z, x, u = -(z+x)/\sqrt{2}, v = -(z-x)/\sqrt{2}$ . First, Alice measures  $\hat{s}'_z$  and Bob  $\hat{s}''_u$ , on each one's member of the same pair. Repeating this experiment determines  $\langle \hat{s}'_z \hat{s}''_u \rangle$ , an ordinary correlation since  $\hat{s}'_z$  commutes with  $\hat{s}''_u$ . A second set of experiments provides  $\langle \hat{s}'_z \hat{s}''_v \rangle$ ; they require a different apparatus since  $\hat{s}'_z \hat{s}''_v$  does not commute with  $\hat{s}'_z \hat{s}''_u$ . A third set of experiments provides  $\langle \hat{s}'_x \hat{s}''_u \rangle$  and a fourth one  $\langle \hat{s}'_x \hat{s}''_v \rangle$ . Students can evaluate as an exercise [45] the quantity  $C \equiv \langle \hat{s}'_z \hat{s}''_u \rangle + \langle \hat{s}'_z \hat{s}''_v \rangle + \langle \hat{s}'_x \hat{s}''_u \rangle - \langle \hat{s}'_x \hat{s}''_v \rangle$ . The result,  $2\sqrt{2}$ , violates Bell's inequality  $|C| \leq 2$  which would hold if the statistical properties of the four observables  $\hat{s}'_z, \hat{s}'_x, \hat{s}''_u, \hat{s}''_v$  could be derived from a single ordinary probability distribution. There is *no joint probability distribution* governing *together* the four observables [46], although probabilities can be assigned separately to each pair  $\hat{s}'_z \hat{s}''_u, \hat{s}'_z \hat{s}''_v, \hat{s}'_x \hat{s}''_u, \hat{s}'_x \hat{s}''_v$ . This *irreparable* theoretical issue has been termed “contextuality loophole” [47].

There is also no joint probability distribution  $P(x, p)$  for the two non-commuting observables  $\hat{x}$  and  $\hat{p}$  of a particle [46]. Heisenberg's inequality should not be regarded as a property of a single physical system, since the two  $q$ -variances  $(\Delta x)^2$  and  $(\Delta p)^2$  must be measured on different systems and hence cannot be interpreted as ordinary variances<sup>32</sup>.

The role of the apparatus is also emphasized by the consideration of *imperfect measurements*, which may be studied as exercises. (i) If S and M are not sufficiently coupled ([13], § 7.3), truncation takes place but the source  $\hat{h}_i$  entering the dynamical equation (16) for  $\hat{R}_{ii}(t)$  is too weak to ensure relaxation of M towards  $\hat{R}_i$  and *registration cannot take place*. An admixture of another  $\hat{R}_j$  ( $j \neq i$ ) spoils the one-to-one correspondence between  $\hat{r}_i$  and  $\hat{R}_i$  in the final equilibrium state  $\hat{D}(t_f)$  of S+M. (ii) If the conservation laws  $[\hat{H}, \hat{\pi}_i] = 0$  are not satisfied (Sec. 8.2 of [13]), the final state of S+M still has an equilibrium form

$$\hat{D}(t_f) = \sum_i q_i \hat{\rho}_i \otimes \hat{R}_i, \quad (42)$$

as in § 4.3.1, but  $q_i$  differs from  $p_i$  and  $\hat{\rho}_i$  differs from  $\hat{r}_i$ . In both cases, the properties (39) and (41) of ideal measurements are violated.

## 6.5. Conceptual structure

Among the many existing approaches to measurement theory, we have presented above ideal measurements as dynamical processes. An abstract formalism describing a set  $\mathcal{E}$  of systems S+A has eventually produced a physical interpretation. Our successive steps comply with the structure of a physical theory, as epistemologically analyzed by Darrigol [22] who distinguishes four ingredients:

- (a) A “*symbolic universe*” made of mathematical entities and structures, associated with the description of the objects under study.
- (b) Basic *theoretical laws* which govern, in this symbolic universe, the behavior of the abstract mathematical images of physical objects.
- (c) *Interpretive schemes* which relate the above formalism to idealized physical experiments. Some mathematical quantities thereby acquire an interpretation and become meaningful in concrete experiments.
- (d) *Approximations* used to adequately set up a symbolic universe and theoretical laws, then to implement this mathematical formalism into the analysis of interpretive idealized experiments.

These four points underlie the above developments. The abstract quantum formalism of § 2.1 and § 2.2 encompasses the points (a) and (b), respectively. We use the term “interpretation” in the sense of point (c): Rather than trying to interpret the quantum formalism itself, we define a model of ideal quantum measurements (§ 3) then formally analyze their process (§ 4).

Approximations (point (d)) are needed, as usual in statistical physics, to solve the equations that govern the dynamics of the compound system S+A, and to explain irreversibility. Moreover, *the interpretation itself* of a measurement process relies on approximations (Appendix C). In particular, the apparent incompatibility between von Neumann's

<sup>32</sup> The Wigner function  $W(x, p)$ , a mathematical representation of the density operator, looks like a probability distribution without having its properties, since it may have negative parts. It is only by focusing on the single observable  $\hat{x}$  (or  $\hat{p}$ ) that one gets an ordinary probability distribution on  $x$  (or  $p$ ), represented by the integral of  $W(x, p)$  over  $p$  (or over  $x$ ), and which produces independently  $\Delta x$  (or  $\Delta p$ ).

reduction and Schrödinger’s dynamics is elucidated owing to approximations which produce, on physically relevant timescales, negligible errors for a large enough apparatus.

In order to overcome the remaining measurement problem, we needed to introduce the postulate  $\mathbb{P}$  which allowed us to theoretically describe the subsets  $\mathcal{E}_i$  of  $\mathcal{E}$  (§ 5). The property  $\mathbb{P}$  appears as a “*module*” as defined by Darrigol [22]. He notes that incorporating in a new theory a “module”, that is, some element of a former theory, is a general procedure which may ensure the compatibility, flexibility and intelligibility of both theories. Here, the purely quantum principles of § 2 are complemented by the ingredient  $\mathbb{P}$  borrowed from pre-quantum physics and supported by experiment, which accounts for the “Heisenberg cut”.

This addition to the formal principles of § 2 has allowed us to set up an interpretive scheme as defined by the above point (c), in which the apparatus plays a major role (§ 6).

## 7. TUTORIAL HINTS

The above material is an account of detailed courses that have been delivered to *master and graduate students or young researchers*, in the framework of doctoral studies or summer schools. At this level, the main text should provide a scheme for more or less thorough series of lectures. They may range from a clear formulation of the measurement problem to its proposed solution. For more advanced audiences, possibly questionable points may be discussed, such as the need of approximations to justify the truncation of off-diagonal blocks, or the status of the postulate  $\mathbb{P}$  facing the standard quantum principles. Exercises are suggested throughout.

Parts of the text may, however, inspire other types of courses.

In *quantum computing or communication*, the data are processed in the form of hidden  $q$ -information, and extraction of ordinary information therefrom is akin to a measurement process. Thus, many ideas issued from measurement theory fit in courses on quantum information. For instance, it is interesting to grasp the physical process of truncation that causes the destruction of some  $q$ -information, a property needed to read out some usable information (§ 6.3 and Appendix B).

Students in *epistemology* having some notions of quantum physics may benefit from lessons, adapted to such an audience, about the conceptual structure of the theory and about its physical interpretation (§ 6 and Appendix C).

Many topics related to measurement processes are suited to illustrate courses of *statistical physics* at undergraduate or graduate level, either as lectures or as exercises (§ 4.2 and Appendices A, B, C). When introducing density operators (formally as in § 2), it is advisable to discuss Schrödinger’s ambiguity to clarify their physical meaning (§ 5 and Appendix D) [39]. Assignment of a quantum state to a system in thermodynamic equilibrium, including broken invariance, appears in §§ 2.3, 3.2.1, 4.3.1 and 5.3. The role of conservation laws is exemplified in §§ 3.2.2, 4.1, 4.3.2 and 5.3. Appendix B presents a pedagogical example of cascade relaxation mechanism, which destroys information about the observables of  $S$  incompatible with the tested quantity  $\hat{s}$ . This model helps to elucidate the irreversibility paradox (Appendix C).

At an elementary level, it is essential to avoid misunderstandings when introducing the quantum concepts and formalisms. Ideal measurements play a major role in the interpretation of quantum mechanics. Therefore, although their complete theory is not accessible to beginners, some ideas extracted from § 2 and § 6 should be instilled in *high school* teaching or in *undergraduate courses*. Students should be told at the earliest possible stage that the quantum formalism is *abstract*, and that a wave function is not a physical property of a particle or a system. A “quantum state” (even pure) does not describe an individual system, but is a mathematical tool for making probabilistic predictions. In this prospect, we advocated the introduction of the terms  $q$ -probabilities,  $q$ -correlations, etc., instead of probabilities, correlations, etc. to distinguish such quantum formal quantities from ordinary ones (§ 2.1.3), a distinction which is essential to discuss specifically quantum properties arising from the non-commutation of observables. Physical meaning emerges from such a formalism only in relation with a specified *context* or a dedicated *apparatus* (§ 6.4). This feature should provide a proper understanding of Born’s rule which arises from the indications of the pointer (§ 6.2), and of von Neumann’s “collapse” (§ 6.3) which is not a dynamical property but an updating of the quantum state based on a selection by the experimenter of one of the possible outcomes. (This demystifying idea is also suitable for popularization of science.)

We close by noting that ideas of quantum measurement theory find applications in various interdisciplinary areas, beyond quantum physics [48–50].

## APPENDICES

## A. EFFECTS OF THE BATH

To fully establish measurement theory on the principles of quantum mechanics, one should solve the dynamical equations (16) for M + B, in the respective eigensectors of S. A standard step in statistical mechanics consists in eliminating the bath B from (16), at second order in the weak coupling  $\hat{H}_{MB}$ , so as to derive from (16) approximate equations for M (see Sec. 4 of [13]). Besides the terms exhibited in (43) below, these dynamical equations for  $\hat{R}_{ij}(t)$  include a retarded non-Hamiltonian part issued from  $\hat{H}_{MB}$ . They govern *solely the measuring device* M owing to the conservation of  $\hat{s}$  which allows the splitting of the equations for  $\hat{D}(t)$  (as in § 4.1 for  $\hat{D}$ ).

For  $i = j$  (“*registration*”), the equation for  $\hat{R}_{ii}(t)$  is exactly the same as for an apparatus M *alone* with Hamiltonian  $\hat{H}_M + \hat{h}_i$ , weakly coupled to a bath at temperature  $T$ . The relaxation of  $\hat{R}_{ii}(t)$ , from  $\hat{R}(0)$  to the canonical equilibrium state  $\hat{R}_i^h$ , taken for granted in § 3.2.2 (Eq. (11)) and § 4.3, can then be justified by applying standard techniques of statistical mechanics to measurement models. For the Curie-Weiss model, a detailed study, including a discussion of imperfect measurements, is presented in Secs. 7 and 8. of [13].

For  $i \neq j$ , the decay of  $\hat{R}_{ij}(t)$  (“*truncation*”) may result from a *decoherence* induced solely by the bath. This occurs for many models (reviewed in [13], Sec. 2) which can inspire exercises. The bath terms may also suppress the recurrences exhibited below in Eq. (49) ([13], § 6.2). However, as illustrated by appendix B, the decay of  $\hat{R}_{ij}(t)$  may also take place without a bath.

## B. TRUNCATION

Among the various mechanisms that can ensure the truncation of  $\hat{D}(t)$  (§ 4.2), we focus here on *destructive interferences due to dephasing*, which are efficient even *in the absence of a bath*. The dynamical equations for M then reduce to

$$i\hbar \frac{d\hat{R}_{ij}(t)}{dt} = [\hat{H}_M, \hat{R}_{ij}(t)] + \hat{h}_i \hat{R}_{ij}(t) - \hat{R}_{ij}(t) \hat{h}_j, \quad (43)$$

with initial condition  $\hat{R}_{ij}(0) = \hat{R}_M(0)$ . The decay of  $\hat{R}_{ij}(t)$  will rely on the large number of degrees of freedom of the pointer, and on the non-Hamiltonian form of (43). For the Curie-Weiss model, this mechanism has been thoroughly explored in Sections 5 and 6 of [13], including discussions about the needed size of parameters, the time scales, the time dependence of correlations, the validity of approximations, the role of the initial state of M, the possibility of recurrences and their suppression, the interplay with the decoherence by the bath. Such developments lend themselves to students’ exercises which enlighten the irreversibility of truncation. We suggest simple ones below.

## B.1. Dephasing mechanism

If all operators  $\hat{H}_M$ ,  $\hat{h}_i$  and  $\hat{R}_M(0)$  commute with one another, Eq. (43) is solved as

$$\hat{R}_{ij}(t) = \hat{R}_M(0) \exp[-i(\hat{h}_i - \hat{h}_j)t/\hbar]. \quad (44)$$

For  $i \neq j$ , the existence of many degrees of freedom for M allows  $\hat{h}_i - \hat{h}_j$  to have a large number of different eigenvalues. Their contributions to  $\text{tr}_M \hat{R}_{ij}(t) \hat{O}$  for “smooth” observables  $\hat{O}$  may then oscillate out of phase, and thus *interfere destructively*, so that such  $q$ -expectation values will decay rapidly ([13], subsection 5.1.2).

The Curie-Weiss model provides a simple illustration. The registering device M is modelled by an Ising magnet involving  $N$  spins  $\frac{1}{2}$  with  $z$ -components  $\hat{\sigma}_z^{(n)} = \pm 1$  ( $1 \leq n \leq N$ ).<sup>33</sup> The pointer observable  $\hat{A}$  in the  $2^N$ -dimensional Hilbert space  $\mathcal{H}_M$  is the magnetization operator  $\hat{M}_z = \sum_{n=1}^N \hat{\sigma}_z^{(n)}$ , which takes macroscopic values  $+M_F$  or  $-M_F$  in the ferromagnetic equilibrium states  $\hat{R}_\uparrow$  or  $\hat{R}_\downarrow$ , with fluctuations of order  $\sqrt{N}$ . At  $t = 0$ , M lies in the metastable

<sup>33</sup> As Pauli matrices, the spin operators have the representation  $\hat{\sigma}_x^{(n)} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ ,  $\hat{\sigma}_y^{(n)} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}$ ,  $\hat{\sigma}_z^{(n)} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ , and similarly for  $\hat{s}_x$ ,  $\hat{s}_y$ ,  $\hat{s}_z$ .

paramagnetic state  $\hat{R}_M(0) = 2^{-N}\hat{I}$ , with which the Ising Hamiltonian  $\hat{H}_M$  commutes. We consider a situation in which the truncation time is much shorter than the registration time, so that the diagonal blocks  $\hat{R}_{\uparrow\uparrow}(t)$  and  $\hat{R}_{\downarrow\downarrow}(t)$  remain practically equal to  $\hat{R}_M(0)$  during this truncation process.

The system S is a spin  $\frac{1}{2}$  with Pauli matrices  $\hat{s}_x, \hat{s}_y, \hat{s}_z$ , the tested observable  $\hat{s}$  being  $\hat{s}_z = \hat{\pi}_\uparrow - \hat{\pi}_\downarrow$ . (Ref. [35] considers the situation for spins greater than  $\frac{1}{2}$ .) The index  $i$  takes two values, denoted by  $\uparrow$  and  $\downarrow$  or  $\pm 1$ , and the initial state of S is represented by a  $2 \times 2$  density matrix  $\hat{r}(0)$ . We take as interaction Hamiltonian

$$\hat{H}_{SM} = \hat{\pi}_\uparrow \otimes \hat{h}_\uparrow + \hat{\pi}_\downarrow \otimes \hat{h}_\downarrow = - \sum_{n=1}^N g \hat{s}_z \otimes \hat{\sigma}_z^{(n)} = -g \hat{s}_z \otimes \hat{M}_z \quad (45)$$

with  $g > 0$ , which favors a pointer value having the same sign as  $s_z$ . The sources  $\hat{h}_i$  in (43) are

$$\hat{h}_\uparrow = -\hat{h}_\downarrow = -g \sum_{n=1}^N \hat{\sigma}_z^{(n)}, \quad (46)$$

which act as external fields  $\pm g$ . The solution (44) of (43) is

$$\hat{R}_{\uparrow\downarrow}(t) = \prod_{n=1}^N \left( \frac{1}{2} \exp \frac{2ig\hat{\sigma}_z^{(n)}t}{\hbar} \right) = \hat{R}_{\downarrow\uparrow}^\dagger(t), \quad (47)$$

and it yields for the state of S+M (note that  $(\pi_\uparrow)_{ij} = \delta_{i,1}\delta_{j,1}$  and  $(\pi_\downarrow)_{ij} = \delta_{i,-1}\delta_{j,-1}$ , while  $\hat{s}_\pm = \frac{1}{2}(\hat{s}_x \mp i\hat{s}_y)$ ):

$$\hat{D}(t) = [r_{\uparrow\uparrow}(0)\hat{\pi}_\uparrow + r_{\downarrow\downarrow}(0)\hat{\pi}_\downarrow] \otimes \frac{1}{2^N} \hat{I} + r_{\uparrow\downarrow}(0)\hat{s}_+ \otimes \hat{R}_{\uparrow\downarrow}(t) + r_{\downarrow\uparrow}(0)\hat{s}_- \otimes \hat{R}_{\downarrow\uparrow}(t). \quad (48)$$

The oscillations exhibited in (47) involve  $2^N$  frequencies, the spectrum of which extends uniformly from  $-Ng/\pi\hbar$  to  $Ng/\pi\hbar$ . In the calculation of the  $q$ -expectation values  $\langle \hat{s}_x(t) \rangle$  and  $\langle \hat{s}_y(t) \rangle$  associated with the marginal state  $\hat{r}(t) = \text{tr}_M \hat{D}(t)$  of S, these oscillations interfere and yield

$$\langle \hat{s}_x(t) \rangle = \text{Tr}_{SM} \hat{D}(t) \hat{s}_x = \langle \hat{s}_x(0) \rangle \cos^N \frac{2gt}{\hbar} \quad (49)$$

(and likewise with  $x \mapsto y$  for  $\langle \hat{s}_y(t) \rangle$ ). At the beginning of the process, for  $t \ll \pi\hbar/4g$ , we have  $\cos 2gt/\hbar \approx \exp(-2g^2t^2/\hbar^2)$ . Hence,

$$\langle \hat{s}_x(t) \rangle \sim \langle \hat{s}_x(0) \rangle e^{-t^2/\tau^2}, \quad \tau^2 \equiv \frac{\hbar^2}{2Ng^2}, \quad (50)$$

fades out on the time scale  $\tau$ , which is *very short* for large  $N$ . Thus, at the very first stage of the interaction of S with the apparatus, the measurement of  $\hat{s}_z$  destroys through  $\hat{H}_{SM}$  the original information about the *observables* of S that do not commute with  $\hat{s}_z$ , which are originally embedded in  $r_{\uparrow\downarrow}(0) = \frac{1}{2}\langle \hat{s}_x(0) \rangle + \frac{i}{2}\langle \hat{s}_y(0) \rangle$  and  $r_{\downarrow\uparrow}(0) = [r_{\uparrow\downarrow}(0)]^*$ .

## B.2. Possible recurrences

The above model suffers from a defect. Although truncation is achieved soon after the beginning of the process, the factor  $\cos^N 2gt/\hbar$  in (49) is periodic, and gives rise to *recurrences*. Long after they have disappeared,  $\langle \hat{s}_x(t) \rangle$  and  $\langle \hat{s}_y(t) \rangle$  return to their initial values (within a sign for odd  $N$ ) at the times  $t_\nu = \nu\pi\hbar/2g \gg \tau$  ( $\nu = 1, 2, 3, \dots$ ), around which they display narrow gaussian peaks. These recurrences originate from a peculiarity of (46): the eigenvalues of  $\hat{h}_\uparrow - \hat{h}_\downarrow$  have the same spacing  $4g$  and a large degeneracy. A more uniform spectrum can let such recurrences disappear.

To illustrate this fact, we improve the model by assuming that the couplings of the tested spin  $\hat{s}$  with the spins  $\hat{\sigma}_z^{(n)}$  of the pointer are not exactly the same (subsection 6.1 of [13]). This dependence substitutes  $g_n = g + \delta g_n$  to  $g$  in (45), (46) and (47). The deviations  $\delta g_n = g_n - g$  are assumed to be small ( $\delta g_n \ll g$ ) and to have a zero average. Accordingly, this spread has a negligible effect on the dynamics of the diagonal blocks  $\hat{R}_{ii}(t)$ , i.e., on the registration process.

In (49),  $\cos^N 2gt/\hbar$  is replaced by  $\prod_{n=1}^N \cos 2g_n t/\hbar$ . The factors of this product are now out of phase, and for  $t = t_\nu = \nu\pi\hbar/2g$ , each one reduces to  $(-1)^\nu \cos(\nu\pi\delta g_n/g)$ . The shape of the peak around  $t_\nu$  remains nearly unchanged,

but its height is strongly reduced. Denoting by  $\delta g^2$  the mean square of the  $\delta g_n$ 's, and assuming that  $\nu\delta g/g \ll 1$ , we find for  $t = t_\nu$  the factor

$$\prod_{n=1}^N \cos \frac{\nu\pi\delta g_n}{g} = \exp \sum_{n=1}^N \ln \cos \frac{\nu\pi\delta g_n}{g} \sim \exp \left( - \sum_{n=1}^N \frac{\nu^2\pi^2\delta g_n^2}{2g^2} \right) = \exp \left( -N \frac{\nu^2\pi^2\delta g^2}{2g^2} \right). \quad (51)$$

Hence, if the dispersion of the couplings  $g_n$  satisfies  $1 \gg \delta g/g \gg 1/\sqrt{N}$ , the initial relaxation as  $\exp(-t^2/2\tau^2)$  is not modified, but the  $\nu$ 'th peak is damped by a factor  $\exp -K\nu^2$ , where  $K \equiv N(\pi\delta g/g)^2/2 \gg 1$ . Thus, for a coupling  $\hat{H}_{\text{SM}} = -\sum_{n=1}^N g_n \hat{s}_z \otimes \hat{\sigma}_z^{(n)}$ , the relaxation exhibited in (50) is not spoiled by recurrences, and the *truncation* after the time  $\tau$  of the off-diagonal blocks of  $\hat{D}(t)$  is *permanent*.<sup>34</sup>

### B.3. Cascade of correlations

Returning to the state (47), (48) of S+M, let us now consider the  $q$ -expectation values of more and more complex observables  $\hat{s}_x \otimes \hat{\sigma}_z^{(n)}$ ,  $\hat{s}_y \otimes \hat{\sigma}_z^{(n)}$ ,  $\hat{s}_x \otimes \hat{\sigma}_z^{(n)} \hat{\sigma}_z^{(n')}$ ,  $\dots$ , astride S and M. As in the evaluation of (49), we find for  $t \ll \pi\hbar/4g$ ,

$$\langle \hat{s}_x \otimes \hat{\sigma}_z^{(n)}(t) \rangle = \langle \hat{s}_x \otimes \hat{m}(t) \rangle \sim \langle \hat{s}_y(0) \rangle \sim \left( \frac{\sqrt{2}}{\sqrt{N}} \frac{t}{\tau} \right) e^{-t^2/\tau^2}. \quad (52)$$

Thus, the  $q$ -correlation<sup>35</sup> of  $\hat{s}_x$  (or  $\hat{s}_y$ ) with the reduced pointer variable  $\hat{m} = \hat{M}/N$ , which is absent in the initial state, *increases then disappears* on the short time scale  $\tau$ . This property should be contrasted with the behavior of  $\langle \hat{s}_z \otimes \hat{m}(t) \rangle$  which characterizes ‘‘registration’’ (§ 4.2), a quantity which rises from 0 to  $M_F/N$  between the times 0 and  $t_f$  under the effect of the interaction of M with the bath B.

The  $q$ -correlations between  $\hat{s}_z$  and an increasing number  $k$  of elements  $\hat{\sigma}_z^{(n)}$  of the pointer (for different values of  $n$ ,  $n'$ ,  $n''$ ) are likewise found, for  $t \ll \pi\hbar/4g$ , as

$$\langle \hat{s}_x \otimes \hat{\sigma}_z^{(n)} \hat{\sigma}_z^{(n')}(t) \rangle \sim -\langle \hat{s}_x(0) \rangle \left( \frac{\sqrt{2}}{\sqrt{N}} \frac{t}{\tau} \right)^2 e^{-t^2/\tau^2}, \quad (53)$$

and

$$\langle \hat{s}_x \otimes \hat{\sigma}_z^{(n)} \hat{\sigma}_z^{(n')} \hat{\sigma}_z^{(n'')}(t) \rangle \sim -\langle \hat{s}_y(0) \rangle \left( \frac{\sqrt{2}}{\sqrt{N}} \frac{t}{\tau} \right)^3 e^{-t^2/\tau^2}, \quad (54)$$

and so on. While being absent at the time  $t = 0$  (no initial correlation between the apparatus A and the tested system S), they begin to be produced after the interaction between S and M has been switched on. Initially, they grow as  $(t/\tau)^k$  with a small amplitude  $\sim N^{-k/2}$ , and, for increasing  $k$ , reach a lower and lower peak later and later, for  $t/\tau = \sqrt{k}/2$ , and then rapidly decay.

Altogether, the decay (50) of  $\langle \hat{s}_x(t) \rangle$  and  $\langle \hat{s}_y(t) \rangle$  is accompanied by an appearance of  $q$ -correlations (52) of  $\hat{s}_x$  or  $\hat{s}_y$  with each spin  $\hat{\sigma}_z^{(n)}$  of M. Then, while the latter disappear in turn, they give way to  $q$ -correlations (53) of  $\hat{s}_x$  or  $\hat{s}_y$  with two spins of M, then with three (54), and so on. Larger and larger numbers  $k$  of degrees of freedom of the pointer are gradually involved, at later and later times  $t \sim \tau\sqrt{k}/2$ , in a *cascade phenomenon*; their  $q$ -correlations with S successively build up a little before fading out<sup>36</sup>

Thus, the  $q$ -information about the observables incompatible with the measured quantity  $\hat{s}_z$ , originally embedded in  $\hat{r}(0)$  as  $\langle \hat{s}_x(0) \rangle$  and  $\langle \hat{s}_y(0) \rangle$ , *flows step by step* towards more and more complicated  $q$ -correlations between S and M, which eventually become physically unattainable and can be disregarded. Altogether, the *irreversibility of von Neumann's reduction* is understood as a discarding of the inaccessible multiparticle  $q$ -correlations between the ‘‘cat’’ operators  $\hat{s}_x$ ,  $\hat{s}_y$  of S and the spins of the macroscopic pointer, which are generated by the dynamics as the result of a cascade.

<sup>34</sup> We focus here on not too large values of  $\nu$ , on the time range  $t \ll \hbar/\delta g$ . For larger values of  $\nu$ , i.e., of time, the irreversible truncation may be ensured by the bath. For this decoherence process after the dephasing, we find in subsection 6.2 of [13] a relaxation time  $\tau \sim N^{-1/4}$  for large  $N$ .

<sup>35</sup> There is no subtractive term  $\langle \hat{s}_x(t) \rangle \langle \hat{\sigma}_z^{(n)}(t) \rangle$  since  $\langle \hat{\sigma}_z^{(n)}(t) \rangle \approx 0$  on the truncation time scale.

<sup>36</sup> The  $q$ -correlations with large values of  $k$  which appear over times  $t \gg \tau$  are discussed in subsections 5.1.3 and 5.3.2 of ref. [13]

### C. CONCEPTUAL NEED FOR APPROXIMATIONS

A quantum measurement, which involves the interaction of the tested system with a macroscopic apparatus, is an irreversible process, and its analysis raises the *irreversibility paradox*. This irreversibility of the process seems to contradict the unitarity of the evolution generated by the Liouville–von Neumann equation. An especially simple illustration is provided by the model of App. B. The exact solution (44) of the equation of motion yields a constant entropy  $S[\hat{D}(t)]$ , and also satisfies  $\hat{R}_{\uparrow\downarrow}(t)\hat{R}_{\uparrow\downarrow}^\dagger(t) = 2^{-2N}\hat{I}$  at all times, *without any decay* whereas the off-diagonal blocks  $\hat{R}_{\uparrow\downarrow}(t)$  must *effectively disappear* physically after some time, a property needed to explain the reduction. Such mathematical properties cannot be tested experimentally, hence they have no physical meaning; in fact, their presence stresses once more the need for approximations (item (d) in § 6.5).

The treatment of App. B elucidates this apparent contradiction. Under reasonable conditions, all physical quantities (50), (52) – (54) vanish for  $t \gg \tau$  as if the off-diagonal blocks  $\hat{R}_{\uparrow\downarrow}(t)$  and  $\hat{R}_{\downarrow\uparrow}(t)$  were chopped off at such times (in spite of the property  $\hat{R}_{\uparrow\downarrow}(t)\hat{R}_{\uparrow\downarrow}^\dagger(t) = 1/2^{2N}$ ). As usual when reconciling statistical mechanics with thermodynamics, this solution of the irreversibility paradox relies on two key points.

On the one hand, the “state” (47), (48) is a *mathematical* object which encompasses the probabilistic predictions that we can make about any physical quantity (end of § 2.1.4). However, when  $t$  increases, this exact state contains more and more *physically irrelevant information* about observables that correlate a very large number  $k$  of constituents (App. B.3). B.3). As such quantities cannot be grasped, neither experimentally nor theoretically, it is legitimate to discard them.

On the other hand, the decays of (50), (52) – (54), that lead to truncation, originate from the large number  $N$  of degrees of freedom of the *macroscopic system* M, resulting in the huge number  $2^{2N}$  of complex elements of the  $2^N \times 2^N$  matrix  $\hat{R}_{\uparrow\downarrow}(t)$ . These approximate decays become mathematically exact in the limit  $N \rightarrow \infty$  and fixed  $g\sqrt{N}$ , for finite values of the time  $t$  and of the number  $k$  of spins involved in the  $q$ -correlations.

Another essential point lies in the consideration of *time scales*. In App. B.1, the decay takes place on the time scale  $\tau = \hbar/\sqrt{2N}g$ , and it is effective for  $t \ll \pi\hbar/4g$ . In the less simplified model of App. B.2, recurrences are eliminated on a much larger time scale  $\hbar/\sqrt{2N}\delta g$  (with  $\delta g/g \gg 1/\sqrt{N}$ ). The comparison between App. B.1 and B.2 also shows that sufficiently *complicated interactions* are needed to ensure irreversibility of the cascade process and unreachably large “Poincaré” recurrence times.

All the above features are general. The quantum dynamical equations (2) or (16) refer to *finite* systems. They are reversible and their *exact* solution cannot provide the result (27) for  $\hat{D}(t_f)$ . However, we have stressed (§ 3.1 and § 4.3) that both the measuring device M and the bath B must be *large*. Then, suitably chosen approximations provide negligible errors for the physically relevant quantities in the limit of a large apparatus, and the use of (27) is justified. As in App. B.3, interactions gradually transfer, within  $\hat{D}(t)$ , physically accessible  $q$ -information towards elusive  $q$ -correlations involving a larger and larger number of degrees of freedom, which are discarded to yield the physical result (27) for  $\hat{D}(t_f)$ .

This loss of irrelevant  $q$ -information is measured by the increase  $S[\hat{D}(t_f)] - S[\hat{D}(0)]$  [30]. The constancy of the von Neumann entropy  $S[\hat{D}(t)]$ , which results from the exact dynamical equation (2), appears as a mathematical property without physical incidence, as in the irreversibility paradox, since the disregarded variables are unreachable.

Besides making calculations feasible, approximations are required for conceptual reasons (§ 6.5, point (d)) [22]. In fact, the *exact state*  $\hat{D}_{\text{exact}}(t_f)$  issued from  $\hat{D}(0)$  through the equation of motion (2) *cannot be given any interpretation*. Strictly speaking,  $\hat{D}_{\text{exact}}(t)$  is a sum of oscillatory terms and has no limit. Two types of *interpretive approximations* enter the derivation of the physical  $\hat{D}(t_f)$ , which relies on independent relaxations of the blocks  $\hat{\mathcal{R}}_{ij}(t) = \hat{\pi}_i\hat{D}(t)\hat{\pi}_j$  of  $\hat{D}(t)$ . For  $j = i$ , M evolves irreversibly towards an equilibrium state  $\hat{R}_i = \text{tr}_B \hat{\mathcal{R}}_i$  characterized by the outcome  $A_i$  of the pointer, a property needed to ensure the *registration*, i.e., the one-to-one relationship between  $A_i$  and  $s_i$  (§ 4.2). For  $j \neq i$ , while the exact equations (16) provide  $\text{Tr}_A \hat{\mathcal{R}}_{ij}(t)\hat{\mathcal{R}}_{ij}^\dagger(t) = [\text{Tr}_M \hat{R}_M^2(0)][\text{Tr}_B \hat{R}_B^2(0)]$ , an approximation is needed to explain the *truncation*, i.e., the *effective* decay of  $\hat{\mathcal{R}}_{ij}(t)$  towards  $\hat{\mathcal{R}}_{ij}(t_f) = 0$ . Without this property, we could not describe in the quantum framework the splitting of the set  $\mathcal{E}$  into subsets  $\mathcal{E}_i$ , since we could not split  $\hat{D}(t_f)$  into a sum of terms  $p_i\hat{r}_i \otimes \hat{R}_i \otimes \hat{R}_B(0)$ .

Thus, approximations, justified in the limit of a large apparatus, appear as essential ingredients in the very *elaboration of an interpretation* of ideal measurement processes.

## D. AMBIGUITY OF DECOMPOSITIONS OF DENSITY OPERATORS

We will prove that, if a non-pure density operator  $\hat{D}$  is expressed as a weighted sum  $\sum_k \lambda_k \hat{D}_k$ , the *separate* terms of this decomposition *cannot be given a physical meaning* if nothing else than  $\hat{D}$  is known. As in the example discussed in § 5.1, it will suffice to exhibit two such decompositions that give rise to a logical contradiction [39].

### D.1. Two-dimensional density operator

We begin with an arbitrary state  $\hat{D}$  in a 2-dimensional Hilbert space  $\mathcal{H}^{(2)}$ , which formally describes a set  $\mathcal{E}$  of spins  $\frac{1}{2}$  or of  $q$ -bits. Expressing the density matrix  $\hat{D}$  on the basis of Pauli matrices as<sup>33</sup>

$$\hat{D} \equiv \frac{1}{2}(\hat{I} + v_x \hat{\sigma}_x + v_y \hat{\sigma}_y + v_z \hat{\sigma}_z), \quad (55)$$

we visualize it as the end point of the 3-dimensional vector  $\mathbf{v}$  which represents the polarization. (To simplify, we shall term “vector”  $\mathbf{v}$  the end point of the vector  $\mathbf{v}$ .) For a pure state  $\hat{D} = |\psi\rangle\langle\psi|$ , the vector  $\mathbf{v}$  lies on the Poincaré–Bloch sphere  $|\mathbf{v}| = 1$ , and we have  $|\langle\psi_1|\psi_2\rangle| = \frac{1}{2}(1 + \mathbf{v}_1 \cdot \mathbf{v}_2)$ ; for a mixed state, in which case  $|\mathbf{v}| < 1$ ,  $\mathbf{v}$  lies inside the sphere.

If we consider two (or more) disjoint sets  $\mathcal{E}_k$  of  $\mathcal{N}_k$  spins, represented by states  $\hat{D}_k$ , their merger produces a set  $\mathcal{E}$  of  $\mathcal{N} = \sum_k \mathcal{N}_k$  spins, represented, according to (3), by the state  $\hat{D}$  given by  $\mathcal{N}\hat{D} = \sum_k \mathcal{N}_k \hat{D}_k$ . In the Poincaré–Bloch formalism, the point  $\mathbf{v}$  associated with  $\hat{D}$  is the *barycenter* (defined by  $\mathcal{N}\mathbf{v} = \sum_k \mathcal{N}_k \mathbf{v}_k$ ) of the points  $\mathbf{v}_k$  associated with  $\hat{D}_k$ . Conversely, consider a mixed state  $\hat{D}$  represented by the point  $\mathbf{v}$  within the unit sphere. It has a mathematical decomposition

$$\hat{D} = |\psi_1\rangle\rho_1\langle\psi_1| + |\psi_2\rangle\rho_2\langle\psi_2| \quad \text{or} \quad \mathbf{v} = \rho_1 \mathbf{v}_1 + \rho_2 \mathbf{v}_2, \quad (56)$$

(with positive real numbers  $0 < \rho_{1,2} < 1$ ,  $\rho_1 + \rho_2 = 1$ ), visualized by a straight line which passes through  $\mathbf{v}$  and crosses the unit sphere at two points  $\mathbf{v}_1$  and  $\mathbf{v}_2$ . Let us consider another decomposition  $\mathbf{v} = \rho'_1 \mathbf{v}'_1 + \rho'_2 \mathbf{v}'_2$ . The two points  $\mathbf{v}_1$  and  $\mathbf{v}'_1$ , and hence the corresponding kets  $|\psi_1\rangle$  and  $|\psi'_1\rangle$ , are different. If  $|\psi_1\rangle$  did describe a physical subset  $\mathcal{E}_1$  of  $\mathcal{E}$  and  $|\psi'_1\rangle$  another subset  $\mathcal{E}'_1$ , there would exist a non-empty physical subset  $\mathcal{E}_1 \cap \mathcal{E}'_1$  simultaneously described by two different states  $|\psi_1\rangle$  and  $|\psi'_1\rangle$ . Such a contradiction arises for any pair of decompositions. Hence, decompositions of  $\hat{D}$  cannot have a physical meaning. (As indicated in § 5.3, additional information, not included in  $\hat{D}$ , is needed to interpret one among the various decompositions.)

The two pure states entering (56) are orthogonal ( $\mathbf{v}_1 = -\mathbf{v}_2$ ) for the unpolarized state  $\mathbf{v} = 0$ . Otherwise, for  $|\mathbf{v}| \neq 0$ , imposing  $\langle\psi_1|\psi_2\rangle = 0$  in (56) would provide only one decomposition of  $\hat{D}$ . However, there is no reason to assume such an orthogonality, since  $\hat{D}$  may have been prepared by a merger  $\mathcal{E}$  of arbitrary sets  $\mathcal{E}_k$  with a loss of information about this construction. Moreover, this assumption would produce an unphysical qualitative difference between states described by  $\mathbf{v} = 0$  (infinity of decompositions) and by the limit  $|\mathbf{v}| \rightarrow 0$  (single decomposition).

We have split above  $\hat{D}$  into two pure states, which cannot be split further. Other decompositions of  $\hat{D}$  may be considered, for which  $\mathbf{v}$  is the barycenter of an arbitrary number of vectors  $\mathbf{v}_k$  lying either on the surface of the unit sphere or inside it. Their ambiguity follows from that of the elementary decompositions of the type (56) [39]. In case the set  $\mathcal{E}$  described by  $\hat{D}$  had been built by randomly mixing pure or non-pure states prepared beforehand, it is impossible to retrieve from  $\hat{D}$  these original states.

### D.2. Arbitrary dimensions

In the general case of a  $n$ -dimensional Hilbert space  $\mathcal{H}^{(n)}$ , an arbitrary density operator  $\hat{D}$  can be diagonalized as

$$\hat{D} = \sum_{k=1}^n |\phi_k\rangle q_k \langle\phi_k| \quad (57)$$

over an orthonormal basis  $|\phi_k\rangle$  of  $\mathcal{H}^{(n)}$ . If  $\hat{D}$  is not pure, at least two of its eigenvalues, say  $q_1$  and  $q_2$ , do not vanish, and  $0 < q_1 + q_2 \equiv q \leq 1$ . Isolating the first two terms of (57), we rewrite  $\hat{D}$  as

$$\hat{D} = q\hat{D}_2 + \sum_{k=3}^n |\phi_k\rangle q_k \langle\phi_k|, \quad (58)$$

where  $\hat{\mathcal{D}}_2 \equiv |\phi_1\rangle\langle q_1/q| + |\phi_2\rangle\langle q_2/q|$  has the same properties as a density operator in the 2-dimensional Hilbert subspace  $\mathcal{H}^{(2)}$  of  $\mathcal{H}^{(n)}$ . The ambiguity of  $\hat{\mathcal{D}}_2$  entails that of  $\hat{\mathcal{D}}$ .

The quantum ambiguity of the decompositions of density operators contrasts with the properties of classical probability distributions [13, 39]. For a classical spin that may take the values  $+1$  or  $-1$  (or for an ordinary bit), the probability distribution  $p_{+1}, p_{-1}$  can be visualized by a point  $x = p_{+1} - p_{-1}$  in the interval  $[-1, +1]$  of a one-dimensional line, which replaces the 3-dimensional Poincaré – Bloch sphere  $|\mathbf{v}| \leq 1$  of (55). Then, the barycentric decomposition  $x = p_{+1} - p_{-1}$  replacing (56) is *the only one*, and there is no ambiguity.

More generally, the density matrices in a  $n \times n$  Hilbert space can be geometrically visualized as the points  $\mathbf{v}$  of a  $(n^2 - 1)$ -dimensional convex region. The extreme points  $x$  of this region, which lie in a  $(2n - 2)$ -dimensional space, represent the pure states. A point  $\mathbf{v}$  associated with a non-pure state has an infinite, continuous number of barycentric representations in terms of extreme points  $x$ . In contrast, the ordinary probability distribution  $p_1, p_2, \dots, p_n$  for  $n$  exclusive events is visualized as a point  $\mathbf{v}$  in a convex  $(n - 1)$ -dimensional region. This region (mathematically called “regular simplex”) has  $n$  discrete extreme points  $x$  representing events known with certainty, in terms of which the barycentric representation of  $\mathbf{v}$  is unique.

### D.3. Pure states versus mixed states

The mathematical distinction between pure and mixed states entails some physical differences. Given the state describing a set of systems, the above ambiguity of decompositions, which impedes to describe subsets, is specific to mixed states [13, 39]. Regarding von Neumann’s entropy  $S$  as a measure of randomness (§ 2.2.4), pure states for which  $S = 0$  appear as the most informative, the least random, or least “noisy” ones.

We present below another physical criterion exhibiting *pure states* as the *least noisy* ones. Consider, in a  $n$ -dimensional Hilbert space  $\mathcal{H}$ , a state  $\hat{r}$  represented by a density matrix having  $k$  non-zero eigenvalues ( $1 \leq k \leq n$ ). The projector  $\hat{\pi}_r$  on the corresponding eigenvectors spans a  $k$ -dimensional Hilbert subspace that we denote by  $\mathcal{H}_r$ . We shall call “*dispersionless*” the observables  $\hat{a}$  that have a vanishing  $q$ -variance on the state  $\hat{r}$ :

$$\langle \hat{a}^2 \rangle - \langle \hat{a} \rangle^2 \equiv \text{Tr } \hat{r} \hat{a}^2 - (\text{Tr } \hat{r} \hat{a})^2 = 0. \quad (59)$$

We introduce the spectral decomposition  $\hat{a} = \sum_i a_i \hat{\pi}_i$  of  $\hat{a}$  in terms of its eigenvalues  $a_i$  and eigenprojectors  $\hat{\pi}_i$ , and denote by  $\mathcal{H}_i$  the  $m_i$ -dimensional Hilbert subspace of  $\mathcal{H}$  spanned by  $\hat{\pi}_i$ . The condition (59) reads

$$\sum_i p_i (a_i - \langle \hat{a} \rangle)^2 = 0, \quad p_i = \text{Tr } \hat{r} \hat{\pi}_i, \quad (60)$$

which implies, for each  $i$ , either  $p_i = 0$  or  $\langle \hat{a} \rangle = a_i$ . These equalities are satisfied only if  $\langle \hat{a} \rangle = a_i$  for one specific value of  $i$ , say  $i = 1$  (so that  $\langle \hat{a} \rangle = a_1$ ) and if  $p_i = 0$  for any  $i \neq 1$ . The latter property is equivalent to  $p_1 = \text{Tr } \hat{r} \hat{\pi}_1 = 1$  or to  $\hat{r} = \hat{\pi}_1 \hat{r} \hat{\pi}_1$ . Hence, starting from the initial state  $\hat{r}$ , a measurement of the dispersionless observable  $\hat{a}$  will always produce the outcome  $a_1$  and will leave  $\hat{r}$  unchanged.

The identity  $\hat{r} = \hat{\pi}_1 \hat{r} \hat{\pi}_1$  implies that  $\mathcal{H}_r$  is a subspace of  $\mathcal{H}_1$ , so that  $1 \leq k \leq m_1 \leq n$ . The considered observable has the form  $\hat{a} = a_1 \hat{\pi}_1 + \hat{b}$ , where the operator  $\hat{b}$ , which belongs to the subspace of  $\mathcal{H}$  complementary to  $\mathcal{H}_1$ , is represented by a  $(n - m_1) \times (n - m_1)$  matrix. Looking for arbitrary dispersionless observables associated with the state  $\hat{r}$ , we take for  $m_1$  its smallest possible value  $k$ . Such observables have therefore the form

$$\hat{a} = c \hat{\pi}_r + \hat{b}, \quad (61)$$

where  $c$  is an arbitrary real number and  $\hat{b}$  is an arbitrary  $(n - k) \times (n - k)$  Hermitean matrix, which depends on  $(n - k)^2$  real parameters.

Altogether, whereas the set of all observables depend on  $n^2$  parameters, the dispersionless ones depend on  $(n - k)^2 + 1$  parameters. For mixed states that encompass the whole Hilbert space ( $k = n$ ), e.g., Gibbs equilibrium states, the only dispersionless observables are the trivial ones  $c\hat{I}$ . In contrast, pure states ( $k = 1$ ) are the least “noisy” ones in the sense that their set of dispersionless observables is the largest possible, depending on  $n^2 - 2n + 2$  free parameters. For pure states, fluctuations occur for the smallest possible set of observables.

### ACKNOWLEDGEMENTS

We wish to thank Jean-Paul Blaizot, Philippe Grangier, Frank Laloë and anonymous referees for their critical reading and comments.
